Ophiostoma novo-ulmi Brasier is the causal agent of Dutch elm disease, which is responsible for widespread mortality of elm (*Ulmus* sp.) trees in North America and Europe. The pathogen is spread by elm bark beetles, which transmit fungal spores into feeding wounds on elm twigs. Mycoviruses in *O. novo-ulmi* were originally described as D-factors, inducing severe debilitation of the fungal host. Later on, several D-factors were identified as mitoviruses and assigned to *O. novo-ulmi* mitoviruses 1–7 based on phylogenetic analysis. The mitoviruses are transmitted through asexual conidia but not through sexual ascospores. Horizontal virus transmission can occur via hyphal anastomosis between vegetative compatible strains. The prevalence of mitovirus-infected isolates was found to be high in clonal populations at the epidemic disease front because of lack of restriction by vegetative incompatibility. In post-epidemic populations, the prevalence of viruses decreased as the diversity of vc types increased. Virus-induced hypovirulence in *O. novo-ulmi* is mainly associated with poor mycelial growth and reduced viability of conidia. This means that much more conidia are required for virus-infected isolates to infect elm trees. A proposed approach for biological control is to use elm bark beetles as carrier for virus-infected fungal conidia and thereby introducing the virus into local pathogen populations.

Hypovirulence in *Sclerotinia sclerotiorum*

The ascomycete fungus *Sclerotinia sclerotiorum* (Lib.) de Bary is a necrotrophic plant pathogen that causes white mold or stem rot on a number of different host plants. This includes important agricultural crop species such as bean, rapeseed, soybean, and lettuce. The global pathogen occurs in temperate and subtemperate regions. The pathogen is homothallic and can form sexual fruiting bodies (apothecia) through self-fertilization. The sexual spores (ascospores) spread by wind and serve as primary source for new infections. The pathogen can also reproduce asexually by the production of sclerotia, which serve as survival structure and dissemination propagules.

Several mycoviruses that can cause hypovirulence in *S. sclerotiorum* have been described (Table 1). Most promising as biological control agent is SsHADV-1 (*Sclerotinia sclerotiorum* hypovirulence-associated DNA virus 1). This virus is among the few DNA mycoviruses that have been described. To date, it is also the only example where purified virus particles can be used to infect a fungal host. Virus particles that were directly applied to leaves were found to suppress infection by *S. sclerotiorum*. In field trials with rapeseed, the preventive application of hyphal fragments containing SsHADV-1 particles significantly reduced Sclerotinia stem rot and increased crop yield.

S. sclerotiorum also harbors a mycovirus in the family *Hypoviridae*, which induces hypovirulence, namely SsHV2 (*Sclerotinia sclerotiorum* hypovirus 2). Fungal strains infected with this mycovirus exhibit reduced mycelial growth, reduced sporulation, and reduced production of sclerotia. In laboratory experiments with detached leaves, a significant variation in virulence among SsHV2-infected strains was observed. Several of these fungal strains showed a strong reduction in virulence, which could lead to candidate agents for biological control of *S. sclerotiorum*.

Sclerotinia sclerotiorum partitivirus 1 (SsPV1) is another mycovirus that confers hypovirulence in *S. sclerotiorum* and related species. SsPV1 induced phenotypic traits in its fungal host include abnormal colony morphology and severe growth reduction. Horizontal transmission of SsPV1 to other fungal strains has been shown to result in transmission of hypovirulence and associated traits.

A strain of a mitochondrial mycovirus, *Sclerotinia sclerotiorum* mitovirus 1 (SsMV1/HCO25) was also found to induce hypovirulence in *S. sclerotiorum*. An infection by this mitovirus has severe effects on the fungus including reduced mycelial growth, reduced sclerotia production, and mitochondrial malformation. On detached leaves of rapeseed and soybean plants, SsMV1/HCO25-infected fungal strains exhibit a strong hypovirulent phenotype with almost no lesion development. Transmission of SsMV1/HCO25 via hyphal contacts converts recipient virulent strains to the hypovirulent phenotype.

Hypovirulence in *Botrytis cinerea*

Botrytis cinerea Pers. is a cosmopolitan necrotrophic pathogen infecting more than 200 plant species in temperate and subtropical climates, some of which are of high economic importance (e.g., grapes, strawberries, solanaceous vegetable). Symptoms vary across plant organs and tissues but include: leaf blight, blossom blight, and post-harvest fruit rots. In spite of the risk of developing fungicide resistance, the pathogen is still mainly controlled using chemical fungicides. In 2001, *Botrytis*-specific fungicides (so called “botryticides”) represented 10% of the world fungicide market.

Although numerous single- or double-stranded mycoviruses have been reported in *B. cinerea* and some have already been sequenced, not all of them are associated with hypovirulence. The mycoviruses that appear to attenuate the virulence of the infected fungal strains include: *Botrytis cinerea* mitovirus 1 (BcMV1, previously named BcDRV), *Botrytis cinerea* RNA virus 1 (BcRV1), *Botrytis cinerea* hypovirus 1 (BcHV1), *Botrytis cinerea* partitivirus 2 (BcPV2), and *Botrytis cinerea* CCg378 virus 1 (Bc378V1). BcMV1 was found in a hypovirulent *B. cinerea* isolate from oilseed rape in China and appears to debilitate mitochondria in hyphal cells. Laboratory experiments showed that BcMV1 can be transmitted both vertically, to asexual conidia, and horizontally, to other fungal strains. Though the horizontal transmission possibility might be regulated by vegetative incompatibility. BcRV1 was isolated from a Chinese hypovirulent isolate of *B. cinerea* from *Berberis* sp. This mycovirus was found to be capable of vertical transmission via macroconidia and horizontally through hyphal anastomosis. The accumulation level of BcRV1 greatly impacts its attenuation effect on the virulence of *B. cinerea*. In contrast to the two previous mycoviruses, infection by BcHV1 reduces fungal virulence without affecting mycelial growth. The attenuated virulence seems to arise from a significant alteration of the expression of genes associated with the formation of infection cushions, which play a central role during the infection process. BcHV1 can be transmitted horizontally through hyphal anastomosis. BcPV2, a partitivirus in the genus *Alphapartitivirus*, was isolated in an atypically pink strain of *B. cinerea*. Hosts infected with this strain showed a normal vegetative growth, and a reduced production of conidia and sclerotia. Importantly, they also showed an attenuated virulence on several crops, including apples, tomatoes, and potatoes. Following hyphal contact, BcHV1 was successfully transmitted to several virulent *B. cinerea* strains. This resulted in an attenuation of both their pathogenicity and the production of conidia and sclerotia. Bc378V1, a member of the family *Partitiviridae*, was found in a wild-type *B. cinerea* strain that was co-infected by another mycovirus that was not characterized further. Laccase activity and sporulation rates were lower in strains co-infected with both mycoviruses relative to the virus-free strain and strains only infected with Bc378V1. Hypovirulence is therefore most likely conferred by the presence of both mycoviruses.

Despite the presence of several mycoviruses reducing the virulence of the infected *B. cinerea* strains, as of yet none have a real potential as a biocontrol agent. The two main limiting factors are a low competitive ability of mycovirus-infected strains relative to mycovirus-free strains, as well as the limited horizontal transmissibility of the mycoviruses due to vegetative incompatibility.

Hypovirulence in *Rosellinia necatrix*

Rosellinia necatrix is an ascomycete fungus, which causes root rot on many woody plant species including grapevine and many fruit trees. It is a necrotrophic pathogen that also occurs as a saprophyte in the soil. The pathogen is difficult to control due to its soil-borne lifestyle. Different mycoviruses have been detected in *R. necatrix* but often these cause symptomless infections. Two mycoviruses were found to confer hypovirulence: *Rosellinia necatrix* megabirnavirus 1 (RnMBV1) and *Mycoreovirus* 3 (MyRV3). Virus particles of both mycoviruses can be used to transfect virus-free *R. necatrix* strains, which subsequently become hypovirulent.

Hypovirulence in *Helminthosporium victoriae*

The plant pathogenic fungus *Helminthosporium victoriae* (F. Meehan & H.C. Murphy) is the causal agent of Victoria blight of oats (*Avena sativa*). At the end of the 1940s, this fungal pathogen resulted in significant yield losses in most of USA's oat-growing regions. Discovery of a hypovirulence-associated mycovirus occurred in a similar way to that for chestnut blight. In the 1950s, fields of "Victorgrain" oats were observed in Louisiana that, despite an infection by *H. victoriae*, showed only limited yield losses. Isolates recovered from blighted plants presented a stunted and highly sectorized growth. This phenotype was transmitted to 'normally' growing colonies via hyphal anastomosis. The phenotype transmission suggested that the reduced virulence observed in the field was due to a transmissible disease of the fungus. It was later shown that diseased *H. victoriae* isolates harbor two viruses, the victorivirus *Helminthosporium victoriae* virus 190S (HvV190S) and the chrysovirus *Helminthosporium victoriae* 145S (HvV145S). Recent studies have provided strong evidence indicating that HvV190S alone is responsible for the hypovirulence in its fungal host. Coincidentally, laboratory experiments revealed that an infection with HvV190S also induces a hypovirulent phenotype in the chestnut blight fungus *Cryphonectria parasitica*. This might open the door to an artificial introduction of HvV190S-caused hypovirulence in other plant pathogenic fungi.

Hypovirulence in *Fusarium graminearum*

Fusarium graminearum Schwabe is the primary causal agent of Fusarium head blight. This is a severe and worldwide disease of wheat, barley and other small-grain cereals. Quite a few mycoviruses have been reported in this pathogen but three of them (FgV1, FgV-ch9, FgHV2) are associated with hypovirulence. *Fusarium graminearum* virus 1 (FgV1) (proposed family Fusariviridae), causes hypovirulence and reduces rate of mycelial growth, increases pigmentation, and inhibits mycotoxin production. It can be transmitted horizontally via hyphal anastomosis and vertically to asexual conidia. *Fusarium graminearum* mycovirus-China 9 (FgV-ch9) was detected in *F. graminearum* strains recovered from cereals in China. FgV-ch9 can be vertically transmitted to asexual conidia. Based on genomic structure and phylogenetic studies this virus belongs to a novel genus in the family Chrysoviridae. At high and medium FgV-ch9 concentration, infected *F. graminearum* strains show reduced mycelial growth and sporulation (conidia and perithecia), abnormal colony morphology, disorganized cytoplasm, and attenuated virulence on wheat and maize. At low virus concentrations the fungus shows no symptoms of an infection. Finally, the third virus, *Fusarium graminearum* hypovirus 2 (FgHV2) belongs to the genus *Alphahypovirus* and negatively affects mycelial growth rate, conidiation, and mycotoxin production of the infected *F. graminearum* strains.

Future Perspectives

The field of fungal virology has made significant progress in our understanding of the biology of mycovirus-fungus interactions. This research has mainly been driven by the potential of mycoviruses to be used for biological control of fungal pathogens. In recent years a large number of novel mycoviruses have been described in various plant pathogenic fungi. Several of these mycoviruses confer hypovirulence and may have potential as biological control agents for plant pathogens. Thus far, the mycovirus-mediated biological control of chestnut blight is the most successful example of its kind when considering practical applications. Importantly, thanks to the recent promising results in mycovirus research, the perspectives are bright for further successful applications of mycoviruses for biological control of plant diseases.

Glossary

Plasmodesmata Microscopic channels connecting the cytoplasm of adjacent cells in plants.

Triple gene block A set of three genes in overlapping reading frames that function together in facilitating cell-to-cell movement of plant viruses.

Introduction

Mycoviruses have been reported from at least 19 virus families, including viruses with double-stranded (ds) RNA, positive-sense (+), single-stranded (ss) RNA, negative-sense (−) ssRNA(−), and RNA reverse-transcribing genomes, plus at least one ssDNA virus. The majority of these viruses are either unencapsidated or have isometric, encapsidated particles. To date only five mycovirus species with filamentous encapsidated particles have been described (Table 1). Two of these have ssRNA(+) genomes and belong to the order *Tymovirales*: Botrytis virus F (BotV-F), family *Gammaflexiviridae* and Botrytis virus X (BotV-X), family *Alphaflexiviridae*. Two others have ssRNA(−) genomes and belong to the order *Mononegavirales*: Sclerotinia sclerotiorum negative-stranded RNA virus 1 (SsNSRV-1), species *Sclerotinia sclerotimonavirus*, family *Mymonaviridae*, and Fusarium graminearum negative-stranded RNA virus 1 (FgNSRV-1). The fifth is a dsRNA virus Colletotrichum camelliae filamentous virus 1 (CcFV-1) which is phylogenetically related to Aspergillus fumigatus tetramycovirus-1 and Beauveria bassiana polymycovirus-1.

The small number of filamentous mycoviruses reported may simply reflect their rarity compared to other types of mycoviruses but historically it may also reflect the methods most often used to detect mycoviruses. For many years the most commonly used method to screen for the presence of mycoviruses was to extract high molecular weight (MW) dsRNAs, indicative of the presence of either dsRNA viruses or the replicative form of ssRNA viruses. Although this simple technique discovered many RNA mycoviruses it does not detect DNA viruses and also fails to detect some ssRNA viruses, as is well documented for some ssRNA plant viruses, such as luteoviruses and some potyviruses. Amongst the mycoviruses BotV-X and BotV-F are examples of viruses not detected by dsRNA analysis. Although these viruses were discovered during screening of Botrytis cinerea isolates for viral dsRNAs they did not yield sufficient quantities of dsRNA for detection by gel electrophoresis and were only found during virus purification by differential centrifugation, from a B. cinerea isolate that had been chosen as a negative control.

More recently, deep sequencing of total RNA extracts from fungi has detected virus sequences that phylogenetic analysis places in families that include filamentous, encapsidated viruses. For example, the genome of Macrophomina phaseolina tobamo-like virus 1 (MpTLV1) contains four ORFs encoding a methyltransferase and helicase, an RdRp, a putative movement protein, and a coat protein, with a gene order and genome organization typical of members of the genus *Tobamovirus*. Although filamentous particles have not been observed the existence of a coat protein gene suggests that encapsidated particles are produced. In other cases genome analysis may show the absence of a coat protein gene, indicating that encapsidated particles are not produced. For example, Sclerotinia sclerotiorum debilitation associated RNA virus (SsDRV) is classified as a member of the family *Alphaflexiviridae*, a predominantly plant virus family, although it lacks a CP gene and consequently does not form encapsidated particles.

Table 1 Summary of characterized flexuous mycoviruses (September 2018)

Virus name	Genome	Order	Family	Genus	Genome size (Kb)	No. of genome segments	Particle size (nm)	Particle type
<i>Botrytis virus X</i>	ss RNA (+)	<i>Tymovirales</i>	<i>Alphaflexiviridae</i>	<i>Botrexvirus</i>	7	1	13 × 720	filamentous nucleoprotein
<i>Botrytis virus F</i>	ss RNA (+)	<i>Tymovirales</i>	<i>Gammaflexiviridae</i>	<i>Mycoflexivirus</i>	7	1	13 × 720	filamentous nucleoprotein
<i>Sclerotinia sclerotimonavirus</i> ^a	ss RNA (−)	<i>Mononegavirales</i>	<i>Mymonaviridae</i>	<i>Sclerotimonavirus</i>	10.0	6	22 × 200–2000	filamentous enveloped nucleoprotein
<i>Fusarium graminearum</i> negative-stranded RNA virus 1	ss RNA (−)	<i>Mononegavirales</i>	Unassigned	Unassigned	9.1	5	35–50 × ~1200	filamentous enveloped nucleoprotein
<i>Colletotrichum camelliae</i> filamentous virus 1 (CcFV – 1)	dsRNA	Unassigned	Unassigned	Unassigned	12.3	8	12–18 × 1000–4427	filamentous nucleoprotein

^aSyn. = *Sclerotinia sclerotiorum* negative-stranded RNA virus 1 (SsNSRV-1).

Botrytis virus F (BotV-F)

Family – *Gammaplexiviridae*

Genus – *Mycovirus*

Genome Structure

BotV-F was the first flexuous mycovirus to be characterized and also the first fully sequenced virus from *B. cinerea*. The genome consists of a single molecule of linear ssRNA(+), 6827 nt in length, excluding the 3'-poly(A) tail. The genomic RNA consists of two major ORFs separated by a 93 nucleotide untranslated region (UTR), a 5'-UTR of 63 nt and a 3'-UTR of 71 nt, followed by a poly(A) tail (Fig. 1). ORF1 contains conserved methyltransferase and helicase motifs, terminating with an opal stop codon (UGA) and yielding a protein of 153 kDa. Readthrough of this codon is expected to extend the protein to 212 kDa that also includes an RNA-dependent RNA polymerase (RdRp) domain. ORF2 encodes the only structural protein, the 32 kDa coat protein. One obvious difference between the genome structure of BotV-F and those of related plant viruses is the apparent lack of a movement protein that many plant viruses encode to mediate the passage of infectious viral material from cell to cell by interaction with the plant host plasmodesmata. However, fungal viruses such as BotV-F presumably do not require movement proteins as the septal pore, which separates individual compartments of the mycelium, is 150–250 nm and therefore unlikely to be a barrier to the movement of mycovirus particles.

Biological Properties

BotV-F was originally detected in *B. cinerea* isolated from strawberry in New Zealand as a co-infection with Botrytis virus X (BotV-X) (genus *Botrexvirus*, family *Alphaflexiviridae*). BotV-F was subsequently detected in *B. cinerea* isolates from grapevine in New Zealand, cucumber in Israel, lettuce in the UK, and tomato and grapevine in France. Surveys of *B. cinerea* isolates from strawberry plants (*Fragaria* sp.) from the Auckland region and isolates from grapevine (*Vitis* sp.) across New Zealand detected BotV-F in 8/59 (13.6%) of isolates. In addition 16% (4/25) of *B. cinerea* isolates from various host plant species around the world also tested positive for BotV-F. Phylogenetic analysis of thirteen BotV-F isolates, based on ~300 bp sequences spanning the intergenic region between ORFs 1 and 2, placed the isolates in three distinct clades. However, the three clades showed no significant correlation with the geographic origin of the isolates suggesting that BotV-F has a long association with *B. cinerea* and has been distributed with its host fungus, most probably in *B. cinerea* infections of plants.

B. cinerea transfected in-vitro with purified BotV-F particles showed changes in hyphal morphology, reduced linear growth in culture, reduced virulence in a *Phaseolus vulgaris* detached leaf assay and significant changes in amino acid, carbohydrate, and fatty acid metabolism.

Virion Morphology

The virions of BotV-F are flexuous nucleocapsid filamentous with a modal length of approximately 720 nm and a diameter of approximately 13 nm (Fig. 2). The virus particles can be partially purified by chloroform treatment of homogenised fungal mycelium and differential centrifugation.

Phylogenetic Relationships

When first characterized in 2001, sequence analysis of BotV-F indicated that it was most similar to plant viruses in the (then) family *Flexiviridae*, although it did not fit well into any of the existing genera. The complete replicase protein showed a highest amino acid identity (22%–23%) to those of the allxivirus, garlic virus X (GVX), the tymovirus, turnip yellow mosaic virus (TYMV), the potexvirus, strawberry mild yellow edge-associated virus (SMYEV), and the vitivirus, grapevine virus B (GVB). In the methyltransferase region, BotV-F showed highest amino acid identity (34%) to the tymovirus, TYMV and the marafivirus, oat blue dwarf virus (OBDV), while in the helicase region it was closer to GVX and SMYEV (28%) and in the RdRp to the allxivirus garlic virus A (GarV-A) (40%); the potexvirus SMYEV (39%), and the capillovirus, cherry virus A (CVA) (39%). The amino acid sequence of the putative coat protein of BotV-F shows highest homology to the conserved central core regions of viruses belonging to the genera *Capillovirus*, *Trichovirus*, and *Vitivirus*, but is unusual in having a long C-terminal region compared with the coat proteins of plant viruses. Another unusual feature of BotV-F, compared to flexuous filamentous ssRNA(+) plant viruses, is the putative

Fig. 2 Electron micrograph of flexuous rod-shaped particles in a partly purified preparation of *Botrytis cinerea* isolate RH106–10, negatively stained with 2% potassium phosphotungstate, pH 4. Bar = 200 nm. From Howitt, R.L.J., Beever, R.E., Pearson, M.N., and Forster, R.L.S., 2001. Genome characterization of Botrytis virus F, a flexuous rod-shaped mycovirus resembling plant ‘potex-like’ viruses. *Journal of General Virology* 82, 67–78.

Fig. 3 Genome organization of Botrytis virus X showing the relative positions of the ORFs and their expression products. Mtr, methyltransferase; Hel, helicase; RdRp, RNA-dependent RNA polymerase; CP, capsid protein. Copyright © 2017, International Committee on Taxonomy of Viruses [ICTV].

read-through opal codon in the replicase, which is more typical of read-through codons found in the bipartite genomes of ssRNA straight rod-shaped viruses such as the tobamoviruses and furoviruses.

In the 9th Report of the ICTV (2011) BotV-F was assigned as the type member of a newly created genus *Mycoflexivirus* within a newly created family *Gammaflexiviridae*, order *Tymovirales*.

Botrytis Virus X (BotV-X)

Family – *Alfalflexiviridae*

Genus – *Botrexvirus*

Genome Structure

The BotV-X genome consists of a single molecule of linear ssRNA(+), 6966 nt in length, excluding the 3′-poly(A) tail. The genome comprises five putative ORFs, a 5′-UTR of 95 nt, untranslated regions of 17 nt separating ORFs 1 and 2, and 6 nt separating ORFs 2 and 3, and a 3′-UTR of 149 nt, followed by a poly(A) tail (Fig. 3). The genome has a 5′ cap immediately followed by the nucleotide sequence GAAAAC, typically found in members of the plant virus genus *Potexvirus*. ORF1 encodes the 158 kDa polymerase. ORF2, which is in the +1 frame relative to ORF1, encodes a 30 kDa putative protein (p30) but nucleotide and amino acid sequences of p30 do not reveal any significant homology with other known sequences. ORF3, which is in the same frame as ORF2, encodes the 44 kDa coat protein and terminates at an amber (UAG) codon. ORF4 and ORF5 both encode putative proteins with an expected molecular mass of ~14 kDa. ORF4 overlaps ORF3 and is in the same frame as ORF1, while ORF5 is in the same frame as ORF2 and ORF3. Neither of these proteins show any significant homology with known viral proteins.

Biological Properties

BotV-X was first discovered infecting an isolate of the plant pathogenic fungus *B. cinerea* from a strawberry plant in New Zealand, which was also infected with BotV-F. BotV-X was subsequently detected in other New Zealand *B. cinerea* isolates from grapevine and tomato.

The transmission rate of BotV-X through asexual conidia is >95% and under experimental conditions transmission has also been shown through sexually produced ascospores from both the male parent (34% transmission) and female parent (53% transmission). Since *B. cinerea* is rarely observed to produce ascospores in nature they presumably play a minor role in virus dispersal but sexual reproduction may provide a mechanism of the virus moving into new vegetatively incompatible groups of the fungus.

Immunofluorescent light microscopy of sections through BotV-X infected fungal tissue and fixed mycelia grown on glass slides, using antibodies raised against BotV-X coat protein expressed in *Escherichia coli*, showed (presumed) virus aggregates in hyphal tips, closely associated with fungal cell membranes and walls, and adjacent to septal pores. Although it is generally assumed that mycoviruses move passively through the cytoplasm it is not known exactly how flexuous viruses of filamentous fungi are transported from cell to cell. The occurrence of virus aggregates next to septa suggests that the septal pores of *B. cinerea* may restrict viral movement, although the presence of viral aggregates on both sides of the septum suggests that movement through septa does occur.

In an apple assay, naturally BVX-infected isolates grew slightly slower (i.e., were less virulent) than virus-free isolates. However, *B. cinerea* isolates transfected in-vitro with purified BotV-X particles showed no significant difference in virulence compared to the isogenic virus free line, in either bean leaf or apple fruit assays. In culture on malt extract agar plates some naturally infected *B. cinerea* isolates showed increased growth rates compared to BotV-X-free isolates.

Virion Morphology

The virions of BotV-X are flexuous nucleoprotein filaments with a modal length of ~720 nm and a diameter of ~13 nm (Fig. 2). The virus particles can be partially purified by chloroform treatment of homogenised fungal mycelium and differential centrifugation.

Phylogenetic Relationships

ORF1 encodes the 158 kDa replicase protein (p158) the amino acid sequence of which shows highest identity to replicases from the allxivirus garlic virus A [GarV-A] (49%) and the potexvirus cymbidium mosaic virus [CymMV] (36%). Amino acid alignments of the three internal conserved methyltransferase, helicase, and RdRp domains of GarV-A show 51%, 55%, and 73% identity, respectively, while in CymMV identity to these regions ranges from 45% to 51%. Phylogenetic analysis of the RdRp region clusters BVX amongst the *Allexivirus* and *Potexvirus* genera but closest to the allxiviruses. The first 211 amino acids of the p44 protein (ORF2) do not show significant homology with known proteins, but the C-terminal 189 amino acids (encoding a 20 kDa protein) show significant identity to the coat proteins of CymMV (35%), the allxivirus, garlic virus X [GarV-X] (34%) and the carlavirus, garlic latent virus [GarLV] (34%). Alignment of the conserved residues in the coat protein, associated with the putative salt bridge and corresponding hydrophobic core in flexuous rod-shaped ssRNA plant viruses, also showed highest amino acid identity to CymMV (65%). Phylogenetic analysis of the putative coat protein gene clusters BotV-X with the genus *Allexivirus*.

Although BotV-X has a different genome structure from both allxiviruses and potexviruses it has a number of properties in common with the viruses of these two genera. While it displays high replicase sequence similarity to the allxiviruses, other features, such as the size of the replicase gene, the overall size of the genome, and the conserved 5' terminal nucleotide sequence, are more typical of potexviruses. In the 9th Report of the ICTV (2011) BotV-X was assigned as the type member of a newly created genus *Botrexvirus* within a newly created family *Alfalexiviridae*.

Sclerotinia Sclerotimonavirus

Family – Mymonaviridae

Genus – Sclerotimonavirus

Genome Structure

The genome of the sclerotimonavirus *Sclerotinia sclerotiorum* negative-stranded RNA virus 1 (SsNSRV-1) is a 10,002 nt ssRNA (–) that lacks a poly(A) tail at the 3' terminus and has an uncapped 5' terminus (Fig. 4). It consists of six non-overlapping ORFs (I–VI), linearly arranged and separated by conserved gene-junction sequences commonly found in mononegaviruses. ORF V encodes the largest protein, which contains a conserved mononegaviral RdRp domain. ORF II appears to encode the two proteins (p43 and p41) that have been isolated from purified nucleocapsids of the virus. In mononegaviruses ORF IV typically encodes glycoprotein G, however it's unlikely that ORF IV of SsNSRV-1 encodes G protein as it is only 186 bp and lacks a putative signal peptide.

Biological Properties

SsNSRV-1 of *Sclerotinia sclerotimonavirus* confers hypovirulence on *Sclerotinia sclerotiorum*. Symptoms include slow growth on potato dextrose agar (PDA), loss of the ability to produce sclerotia, loss of pathogenicity on rapeseed and zigzag growth of hyphal tips in culture (possibly due to loss of growth polarity). SsNSRV-1 infected *Sclerotinia sclerotiorum* has been isolated from both soybean and rapeseed in China and is widely distributed, having been detected in five provinces (Anhui, Heilongjiang, Hubei, Jiangxi, and Shaanxi) representing a range of climatic regions.

Fig. 4 Virion morphology and genome organization and expression map of *Sclerotinia sclerotiorum* negative-stranded RNA virus 1 (SsNSRV-1). (a) Morphology and structure of SsNSRV-1 virions and nucleoprotein–RNA complexes (RNPs). Particles and RNPs were purified from mycelia of strain AH98 and Ep-1PNA367-PT2 and negatively stained with 2% PTA (W/V, pH 7.4) (scale bars are shown at the bottom). (A) Filamentous, possibly enveloped virions and RNPs. (B) Purified tight or loose coils of RNPs. (C) Rings that make up the coils and NP monomers. (b) Genomic organization of SsNSRV-1 showing all six ORFs. (c) Deduced transcription map of SsNSRV-1 based on 5′- and 3′-RACE. Fig. 1 From, 2015.008a-gM.A.v3.Mymonaviridae.pdf (https://talk.ictvonline.org/files/ictv_official_taxonomy_updates_since_the_8th_report/m/animal-dsrna-and-ssrna-viruses/5831). Modified from Liu, L., Xie, J., Cheng, J., *et al.*, 2014. Fungal negative-stranded RNA virus that is related to bornaviruses and nyaviruses. *Proceedings of the National Academy of Sciences of the United States of America* 111, 12205–12210.

Virion Morphology

The virions of SsNSRV-1, purified from mycelia and negatively stained with 2% PTA, are filamentous, 25–50 nm in diameter and 200–2000 nm in length, and appear to be enveloped (Fig. 4). The nucleocapsids are long, flexible, helical structures, which, when tightly coiled, have a diameter of 20–22 nm and possibly contain two nucleoproteins of ~43 kDa (p43) and ~41 kDa (p41), both translated from ORF II. The nucleocapsids of SsNSRV-1 (as observed by TEM) consist of tightly stacked turns and have variable

appearance, including both relatively rigid rods and loosely coiled helices, similar to the RNA–nucleoprotein complexes (RNPs) reported from other mononegaviruses. Electron micrographs of ultrathin fungal hyphal sections show tubular structures, similar to the purified virions, consisting of nucleocapsids enclosed within an outer membrane. Mononegaviruses typically have enveloped virions but the apparently stable filamentous shape of SsNSRV-1 is unusual as most mononegaviruses have pleomorphic virions.

Phylogenetic Relationships

SsNSRV-1 shares a number of general characteristics in common with mononegaviruses, although there are some differences. Mononegaviruses typically have nonsegmented ssRNA(–) genomes, 8.9–19 kb in size and virions of variable morphologies that are enveloped with a phospholipid membrane originating from the host. Phylogenetic analysis of RdRp amino acid sequences clusters SsNSRV-1 with viruses of the families *Nyamiviridae* and *Bornaviridae* (order *Mononegavirales*), although SsNSRV-1 does not conform to the typical five-gene pattern (N-P-M-G-L) of mononegaviruses as it has six ORFs, and the NPs are encoded by ORF II instead of ORF I. The 2018 ICTV report classifies SsNSRV-1 in a newly created genus *Sclerotimonavirus*, family *Mymonaviridae*, Order *Mononegavirales*.

Fusarium Graminearum Negative-Stranded RNA virus 1

Family – Mymonaviridae (?)

Genus – Unclassified

Genome Structure

Fusarium graminearum negative-stranded RNA virus 1 (FgNSRV-1) has a ss RNA(–) genome of 9072 nucleotides in length, consisting of five ORFs (ORF I–V) of 774, 1167, 238, 5893 and 552 nt, respectively, and lacks a poly (A) tail at the 3′-terminus. The five ORFs putatively encode five proteins (P I to P V) with predicted molecular masses of 29.1, 42.8, 6.2, 221.6, and 21.1 kDa, respectively. The 3′-untranslated region (UTR) and 5′-UTR are 126 nt and 220 nt long, respectively, and have perfect complementarity for the first six residues (3′-UCCUGC–GCAGGA-5′), a feature common among mononegaviruses. The P II and P IV proteins show significant amino acid sequence similarity to the nucleoprotein N and large protein L of SsNSRV-1 sequences, with the P IV containing mononegaviral-like L polymerase domains. However, similar to SsNSRV-1, the genomic arrangement of FgNSRV-1 does not follow the basic five-gene pattern (N-P-M-G-L) of typical mononegaviruses, the N protein being encoded by ORF II, rather than ORF I, as in most other known mononegaviruses.

Biological Properties

FgNSRV-1 was originally isolated from the plant pathogenic fungus *Fusarium graminearum*. It has no discernable impact on host morphology, mycelial growth, biomass, conidia production, or virulence.

Particle Morphology

The virions of FgNSRV-1 (purified from mycelia) are filamentous, 35–50 nm in diameter and ~1200 nm in length. Short rod-like particles and loose nucleocapsid-like helical structures, similar to the condensed nucleocapsid structures of SsNSRV-1, have also been observed. Given the similarities between FgNSRV-1 and SsNSRV-1, it is possible that the FgNSRV-1 virions are also enveloped by a membrane.

Phylogenetic Relationships

FgNSRV-1 shows high sequence similarity (93.9%–98.8% nucleotide; 97.3%–100% amino acid) to soybean leaf-associated negative-stranded RNA virus 1 (SsNSRV-1), a virus of unknown morphology identified in a soybean leaf metatranscriptomic study. The putative nucleoprotein (P II) and RNA polymerase (P IV) also show significant homology to mononegaviruses with phylogenetic analysis of entire polymerase sequences indicating that FgNSRV-1 is related to the ssRNA(–) mycovirus SsNSRV-1, suggesting that FgNSRV-1 can be classified in the family *Mymonaviridae*.

Colletotrichum Camelliae Filamentous Virus 1

Family – Unclassified

Genus – Unclassified

Genome Structure

The genome of *Colletotrichum camelliae* filamentous virus 1 (CcFV-1) consists of eight separate dsRNAs, of 2444, 2253, 2012, 1299, 1122, 1085, 1053, and 990 bp. DsRNAs 1, 2, 3, 4, 6, and 7 each consist of a single ORF, while dsRNAs 5 and 8 each contain

two ORFs (one >200 aa, the other <50 aa). DsRNA 1 shares 47% amino acid identity with the RNA-dependent RNA polymerase (RdRp) of *Aspergillus fumigatus* tetramicrovirus-1 (AFuTmV-1) and low similarities to the dsRNA1 of *Alternaria tenuissima* virus (ATV), *Cladosporium cladosporioides* virus 1 (CcV-1), and *Botryosphaeria dothidea* virus 1 (BdRV1). The remaining RNAs show no detectable similarity with any known viral RNA sequences. The predicted protein from ORF 1 clusters CcFV-1 with AFuTmV-1, BdRV1, *Beauveria bassiana* polymycovirus-1 (BbPmV-1), and *Beauveria bassiana* polymycovirus-2 (BbPmV-2), separate from other dsRNA viruses and closer to ssRNA(+) viruses belonging to the *Caliciviridae*. It has been suggested that CcFV-1 may be an intermediate link between dsRNA and ssRNA(+) viruses. The protein coded by dsRNA 3 of CcFV-1 is highly similar to the methyltransferase of various bacteria but the functions of the remaining putative proteins are unknown.

Biological Properties

CcFV-1 is a dsRNA virus that was first reported from an isolate of the plant pathogenic fungus *Colletotrichum camelliae*, from tea (*C. sinensis* (L.)) in China. CcFV-1 infected *C. camelliae* exhibited different morphology and pigmentation from virus-free isolates and showed reduced growth rates (5.4 versus 6.3–6.5 mm/day) and reduced virulence with lesion lengths of 1.0 mm compared to 6.1–14.9 mm for virus free isolates. The CcFV-1 infected isolate also showed cytological abnormalities in ultra-thin hyphal sections observed by TEM, including the formation of large membranous vesicles that contained virus-like particles with a width similar to those of the CcFV-1.

Virion Morphology

CcFV-1 infected cultures contain non-enveloped flexuous filamentous particles with widths ranging from 11.9 to 17.7 nm and lengths from 1001 to 4427 nm, with analysis of particles from different fractions of ultracentrifuged sucrose gradients indicating that dsRNAs 1–8 are separately encapsidated. DsRNA 4 codes for the capsid protein, as demonstrated by immunosorbent electron microscopy, Western blotting and indirect enzyme-linked immunosorbent assay, using antisera produced to purified P4 protein.

Phylogenetic Relationships

Colletotrichum camelliae filamentous virus 1 is currently an unclassified virus species. Although the RdRp of CcFV-1 shows some degree of identity to the RdRps of AFuTmV-1, BdRV1, BbPmV-1, and BbPmV-2, the first three of these viruses are capsidless with genomes consisting of 4–5 dsRNAs, while BbPmV-2 has 7 dsRNAs and is possibly capsidless or may form bacilliform virus-like particles. In contrast CcFV-1 forms encapsidated filamentous particles and has eight dsRNAs. In addition the RdRp of CcFV-1 appears to be in an intermediate position between those of ssRNA(+) viruses ssRNA(+) viruses of the extended picorna-like superfamily such as caliciviruses, astroviruses, and picornaviruses, and dsRNA viruses. It has been proposed that CcFV-1 may have originated from a ssRNA(+) viral ancestor belonging to clades three or six of the picorna-like superfamily although the CP has no detectable sequence similarity with those of known filamentous ssRNA(+) plant viruses.

Relationships Between Filamentous Viruses From Fungi and Plants

Mycoviruses have been reported from at least 19 virus families and one genus, eleven of which (*Barnaviridae*, *Chrysoviridae*, *Deltaflexiviridae*, *Gammaplexiviridae*, *Genomoviridae*, *Hypoviridae*, *Megabirnaviridae*, *Myonnaviridae*, *Narnaviridae*, *Quadriviridae*, and *Botybirnavirus*) currently include only fungal viruses. The other nine families include viruses from a range of hosts: *Alphaflexiviridae* (fungi and plants), *Amalgaviridae* (fungi and plants), *Botourmiaviridae* (fungi and plants), *Endornaviridae* (fungi and plants), *Metaviridae* (fungi, invertebrates, plants and vertebrates), *Partitiviridae* (fungi, plants, protozoa), *Pseudoviridae* (fungi, algae, invertebrates, plants, vertebrates), *Reoviridae* (fungi, invertebrates, plants and vertebrates), *Totiviridae* (fungi and protozoa), although in the majority of cases the fungal viruses are classified in distinct genera. Isometric encapsidated mycoviruses are relatively common and are found in at least six of these families and the one genus, but to date (2019) only five encapsidated filamentous mycoviruses have been fully sequenced and described. Although these five filamentous mycoviruses are taxonomically diverse they have one important factor in common, they are all from plant pathogenic fungi.

BotV-F and BotV-X, are ssRNA(+) and belong to the order *Tymovirales* which contains predominantly plant viruses. SsNSRV-1, belonging to the species *Sclerotinia sclerotimonavirus*, and FgNSRV-1, as yet unassigned to a species, have ssRNA(–) genomes and belong to the order *Mononegavirales*, which includes viruses from a wide range of hosts, including vertebrates, invertebrates and plants. However, the filamentous virions of SsNSRV-1 and FgNSRV-1 are somewhat different from other members of the *Mononegavirales* where the virions are typically spherical, bacilliform or plemorphic, although the nucleocapsids may have a filamentous form. The fifth virus is a dsRNA virus CcFV-1, which is phylogenetically related to the unclassified viruses AFuTmV-1 and BbPmV-1. However, the particles of CcFV-1 have a more defined filamentous structure than the other two viruses, which do not encode a conventional CP and are described as being non-conventionally encapsidated, since they encode a proline/alanine/serine (PAS)-rich protein which most likely coats the viral dsRNA.

Interestingly, despite the apparent scarcity of flexuous filamentous mycoviruses, the first two filamentous mycoviruses to be characterized, BotV-X and BotV-F, were found in the same *B. cinerea* isolate. While they differ in genome structure the genomes are of a similar size and virus purification from the co-infected *B. cinerea* isolate yielded only one size of flexuous filamentous particle, indicating that the two viruses have similar-sized particles. BotV-X and BotV-F show only low to moderate sequence identity to each other in the replicase and coat protein genes and there is no significant similarity between other putative proteins encoded by the two genomes. However, the replicase genes of both viruses shows greatest similarity to plant viruses belonging to the order *Tymovirales*, with a highest amino acid identity of 73% between the RdRp of BotV-X and the plant virus GarV-A. While this is remarkably high for interviral homology between plant and fungal viruses there are many examples of homology between plant and fungal viruses from a range of viral families including the *Endornaviridae*, *Totiviridae*, *Chrysovriidae*, *Amalgaviridae*, and *Partitiviridae*. Despite some sequence similarities the genome structures of BotV-F and BotV-X are distinct from those of the plant virus families of the *Tymovirales*, one obvious difference being the absence of a gene encoding a movement protein in BotV-X and BotV-F. In plant viruses of the *Tymovirales*, movement proteins, which interact with plant host plasmodesmata to allow passage of infectious viral material from cell to cell, are present either as a single polypeptide (e.g., *Capillivirus*, *Vitivirus*) or as a triple gene block (e.g., *Allexivirus*, *Potexvirus*). The lack of a movement protein in BotV-X and BotV-F is a feature consistent with the lack of plasmodesmata or similar restrictions to movement in their fungal host.

The remarkably high sequence similarity between the replicase of BotV-X and that of the plant allexivirus, GarV-A, may indicate a relatively recent divergence from a common ancestor. Since *B. cinerea* has an extremely wide host range, including alliums, a possible scenario is that historically *B. cinerea* acquired a plant virus, such as GarV-A, that was infecting the same host and this virus has subsequently lost unnecessary parts of the genome, such as the movement protein gene.

SsNSRV-1 and FgNSRV-1 are also found in plant pathogenic fungi and are phylogenetically related to mononegaviruses that collectively infect a range of hosts, including plants. Similar to BotV-X and BotV-F, there are differences in genome organization between FgNSRV-1 and SsNSRV-1 and related viruses from other hosts. There are also differences in particle morphology, the virions of SsNSRV-1 and FgNSRV-1, which are filamentous, and the virions of other members of the *Mononegavirales* which are typically spherical, bacilliform or pleomorphic, although the nucleocapsids may take on a filamentous form. As with BotV-X and BotV-F the pathogenic association between the fungal host and plants potentially provides an opportunity for the fungus to acquire a plant virus that becomes modified over time. Although most plant viruses do not have lipoprotein envelopes, some, such as members of the ssRNA(-) families *Bunyaviridae* and *Rhabdoviridae* (order *Mononegavirales*) have lipid based envelopes, which are important for specific interaction with their insect vectors. While there is currently no evidence for insect vectors of mycoviruses the envelopes of SsNSRV-1 and FgNSRV-1 virions would be consistent with these viruses being derived from insect transmitted plant viruses.

Shared lineages between plant and fungal viruses are common with both plant and fungal viruses belonging to at least twelve ICTV-recognized families, with phylogenetic evidence of common ancestry. In addition it has been shown that some fungal viruses are able to replicate in plants cells and vice versa. For example the two mycoviruses *Penicillium aurantiogriseum* totivirus-1 and *Penicillium aurantiogriseum* partitivirus-1 are able to replicate in protoplasts of the plant species *Nicotiana benthamiana* and *Nicotiana tabacum*, while the plant virus, cucumber mosaic virus, is able to form a stable infection in cultures of the fungus *Rhizoctonia solani*. It seems less likely that mycoviruses would be acquired by and form an ongoing infection in plants, because of the lack of movement proteins required for systemic movement in plants. However, the possibility should not be totally discounted as it has been proposed that plant ourmiaviruses, which have a tripartite ssRNA(+) genome, have arisen from a narnavirus (monopartite genome) that acquired additional RNAs that encode a movement protein.

Although the dsRNA virus (CcFV-1) was found in the plant pathogen *Colletotrichum camelliae* it shares a highest amino acid identity of 47% with the RNA-dependent RNA polymerase (RdRp) of AfuTmV-1, a virus from the human fungal pathogen *Aspergillus fumigatus*. However it also shares low identity to the dsRNA-1 of ATV, CcV-1, and BdRV1 from the plant pathogenic fungi *Alternaria tenuissima*, *Cladosporium cladosporioides* and *Botryosphaeria dothidea*, respectively. This raises the possibility that CcFV-1 may be derived from a plant virus, although none of the characterized dsRNA plant viruses have long filamentous particles.

The increasing use of deep sequencing is detecting additional, often unencapsidated, mycoviruses with some sequence identity to known filamentous viruses. For example, members of the family *Deltaflexivirus* (order *Tymovirales*), *Fusarium graminearum* deltaflexivirus 1 (FgDFV1), *Sclerotinia sclerotiorum* deltaflexivirus 1 (SsDFV1), and soybean leaf-associated *mycoflexivirus* 1 (SlaMyfV1), are distantly related to viruses of the order *Tymovirales*, although none of these viruses produce coat proteins. However, in other cases it is unknown whether presumed virus sequences belong to viruses that produce encapsidated filamentous particles and further investigation, including virus purification and electron microscopy is required to determine the nature of the virions.

This is an update of R.B. Wickner, H. Edskes, T. Nakayashiki *et al.*, Prions of Yeast and Fungi, In Encyclopedia of Virology (Third Edition), edited by Brian W.J. Mahy and Marc H.V. Van Regenmortel, Elsevier Ltd., 2008, doi:10.1016/B978-012374410-4.00407-6.

Glossary

Nonchromosomal gene A gene that segregates 4 + :0 – in meiosis and can be transferred by cytoplasmic mixing, in contrast to chromosomal genes that segregate 2 + :2 – in meiosis, and are not transferred by cytoplasmic mixing.

Nonsense suppressor tRNA A mutant transfer RNA that recognizes a translational stop codon and inserts an amino acid thus allowing the peptide chain to continue.

Introduction and History

The word prion, meaning “infectious protein” without need for a nucleic acid, was coined to explain the properties of the agent producing the mammalian transmissible spongiform encephalopathies (TSEs). The yeast and fungal prions were identified by their unique genetic properties which were unexpected for any nucleic acid replicon, but specifically predicted for an infectious protein.

[PSI] was described by Brian Cox in 1965 as a nonchromosomal genetic element of *Saccharomyces cerevisiae* that increased the efficiency of a weak nonsense suppressor transfer RNA (tRNA). [URE3] was described by Francois Lacroute as a nonchromosomal gene that relieved nitrogen catabolite repression, allowing expression of genes needed for utilizing poor nitrogen sources even when a good nitrogen source was available. The [Het-s] prion was described in 1952 by Rizet as a nonchromosomal gene needed for heterokaryon incompatibility in *Podospora anserina*. In 1994, we showed that [URE3] and [PSI +] were prions based on their genetic properties (see below). The [PIN] prion of yeast was discovered in 1997 by Derkatch and Liebman in their studies of de novo generation of the [PSI] prion. There are now an array of prions known in yeast ([Table 1](#)).

Genetic Signature of a Prion

Viruses of yeast and fungi generally do not exit one cell and enter another, but spread by cell–cell fusion, as in mating or heterokaryon formation. Infectious proteins (prions) should likewise be nonchromosomal genetic elements. To distinguish prions from replicating nucleic acids, three genetic criteria were proposed ([Fig. 1](#)): (1) If a prion can be cured, it can reappear in the cured strain at some low frequency. (2) Overproduction of the protein capable of being a prion should increase the frequency of the prion arising de novo. (3) If the prion produces a phenotype by the simple inactivation of the protein, then this phenotype should resemble the phenotype of mutation of the gene encoding the protein, which gene must be needed for prion propagation.

All three criteria were satisfied by [PSI] and [URE3], strongly indicating, perhaps proving, that they were prions. The [Het-s] prion of *P. anserina* and the [PIN] prion of *Saccharomyces cerevisiae* were likewise proved by application of the same genetic criteria, but because their prion form produces the phenotype, rather than the absence of the normal form, the prion protein gene is needed for propagation of the prion, but the phenotype of the prion is not the same as mutants in the prion protein gene.

Self-Propagating Amyloid as the Basis for Most Yeast Prions

The finding that Sup35p, Ure2p, and HET-s were protease resistant and aggregated in prion-containing cells, and that these proteins (and particularly their prion domains ([Fig. 2](#))) would form amyloid in vitro indicated that a self-propagating amyloid ([Fig. 3](#)) was the basis of these prions. This was confirmed by the finding that the corresponding prions were transmitted by introduction of amyloid formed in vitro from the recombinant proteins. In some cases it was shown that the soluble form or nonspecific aggregates of the protein were ineffective. This argues that the respective amyloids are not by-products or a dead-end stage of these prions, but are themselves the infectious material. All infectious Ure2p amyloids are larger than about 40-mer size. Amyloid formed in vitro is capable, for at least [PSI] and [URE3], of transmitting any of several prion variants. This implies that the amyloids can have any of several structures. Strong variants of [PSI +] (those

Table 1 Prions of *Saccharomyces cerevisiae* and *Podospora anserina*

Prion	Prion protein	Prion phenotype	Normal protein function
[URE3]	Ure2p	Derepressed genes for utilizing poor nitrogen sources in presence of a good nitrogen source; slow growth	Repression of genes for utilizing poor nitrogen sources in presence of a good nitrogen source
[PSI ⁺]	Sup35p	Readthrough of termination codons; slow growth; death (depends on prion variant)	Translation termination
[PIN ⁺]	Rnq1p	Rare generation (by cross-seeding) of [PSI ⁺] or [URE3]	none known
[OCT ⁺]	Cyc8p	Slow growth; impaired mating and sporulation	transcription repressor subunit
[SWI ⁺]	Swi1p	Poor growth on raffinose, galactose or glycerol	chromatin remodeling subunit
[MOT ⁺]	Mot3p	Inappropriate derepression of anaerobic genes; colony polymorphisms	transcription regulator
[MOD ⁺]	Mod5p	Partial azole-resistance; slow growth	tRNA isopentenyltransferase
[BETA]	Prb1p	Active protease B (non-amyloid prion)	Active protease B (this is a functional prion)
[Het-s]	HET-s	Heterokaryon incompatibility	Heterokaryon incompatibility (this is a functional prion)

Note: All but [BETA] are amyloid-based prions. [Het-s] is a prion of the filamentous fungus *Podospora anserina*, and the others are prions of *S. cerevisiae*.

Fig. 1 Genetic signature of a prion. Among nonchromosomal genetic elements, those with the three properties shown here must not be nucleic acid replicons and are almost certainly prions. However, only prions for which the prion form of the protein is inactive (such as [URE3] or [PSI]) will have the third property. The [Het-s] and [PIN⁺] prions are active forms of the HET-s protein and Rnq1 protein, respectively and have the first and second properties but not the third.

Fig. 2 Prion domains. The prion domains of Ure2p, Sup35p, and HET-s are largely unstructured in the native form and in β -sheet in the prion form.

Fig. 3 Infectious amyloids of yeast prion proteins have an in-register parallel folded β -sheet architecture. It is suggested that the amyloids of different prion variants differ in the locations of the folds of the sheets (i.e., the turns of the strands). The in-register architecture is maintained by the favorable interactions among identical side-chains. The same interactions force the new monomer joining the end of the filaments to align in-register and thus have the turns in their strands at the same location as molecules already in the filament. This constitutes conformational templating.

with a more pronounced phenotype) are based on shorter, more fragile amyloid filaments with a shorter β -sheet region than are weak [PSI⁺] variants.

Shuffling Prion Domains and Amyloid Structure

The prion domains (Fig. 2) of Ure2p and Sup35p are quite rich in Asn and Gln residues, and nearly the entire sequence of Rnq1p, the basis of the [PIN] prion, is rich in these amino acids. However, many Q/N-rich proteins are not capable of being prions. Thus, it was assumed that specific sequences in the known prion domains were important for prion formation. The Sup35 prion domain has octapeptide repeats much like those in PrP (the mammalian prion protein), and deletion or duplication of these showed substantial effects on prion generation. In addition, single amino acid changes in the prion domain of Sup35p blocked prion propagation.

To critically test whether the Ure2p prion domain had sequences essential for prion development, the entire Q/N-rich region (residues 1–89) was randomly shuffled (without changing the amino acid content) and each of five shuffled sequences were inserted into the chromosome in place of the normal prion domain. Surprisingly, each of these five shuffled sequences could support prion generation and propagation, although one was rather unstable. Each protein with the shuffled sequence could also form amyloid *in vitro*. This showed that it was the amino acid content of the Ure2p prion domain that determines prion formation, and that sequence plays only a minor role.

Similarly, five shuffled versions of the Sup35p prion domain were each inserted in place of the normal sequence. Again, all five shuffled versions allowed formation and propagation of a [PSI⁺]-like prion. It is likely that the effects of deletion or duplication of the octapeptide repeats observed on prion formation or propagation were due to changes in the length or composition of the prion domain. It appears that repeats *per se* are not important for prion generation or propagation.

Shuffleable Prion Domains Suggests Parallel In-Register β -Sheet Structure

Amyloids are β -sheet structures, but there are at least three kinds of β -sheets. Antiparallel β -sheets have adjacent peptide chains oriented in opposite directions: N->C next to C->N. This results in pairing of largely nonidentical residues. A β -helix also involves pairing of largely nonidentical residues, although they are within the same peptide chain. A parallel β -sheet pairs identical residues if it is in-register, but in principle, one could have an out-of-register parallel β -sheet, in which case nonidentical residues would be bonded to each other.

Prion propagation (and amyloid propagation in general) is a very sequence-specific process. For example, a single amino acid change (at residue 138) can block propagation of scrapie in tissue culture. Humans are polymorphic at PrP residue 129 with roughly equal numbers of alleles encoding M and V. Either M/M or V/V individuals can get Creutzfeldt–Jakob disease (a human prion disease), but M/V heterozygotes rarely do. Similarly, a single amino acid change in the prion domain of Sup35p can block propagation of [PSI⁺] from the normal sequence, but the mutant Sup35p can itself become a prion nonetheless. Thus, if a prion amyloid has an antiparallel, parallel out-of-register, or β -helix structure, there must be some form of complementarity between bonded residues. Shuffling such a sequence would be expected to destroy the complementarity. In contrast, shuffling the sequence of a parallel in-register β -sheet would still leave identical residues paired. This suggested that prion domains that can be shuffled without destroying their prion-forming ability are forming parallel in-register β -sheets.

Infectious Prion Amyloids Have In-Register Parallel Folded β -sheet Architecture

Solid-state NMR experiments, combined with mass per filament length determinations, have shown that the prion domains of Sup35p, Ure2p and Rnq1p are each folded in-register parallel β -sheet structures, like the architecture of such pathologic amyloids of human A β , amylin/IAPP, Tau, and alpha-synuclein. In contrast, the functional prion [Het-s] is composed of amyloid of the HET-s protein having a β -helix structure (Fig. 3).

Prion Variants and the Species Barrier

A single protein or peptide can be the basis of a wide variety of prion “strains” or “variants”, based on differing conformations of the protein in the amyloid, each of which is self-propagating. The manifestation of prion variant differences may be strength of the prion phenotype, stability of prion propagation, sensitivity to the overproduction or deficiency of various chaperones or non-chaperone proteins, or the sensitivity to the various endogenous anti-prion systems (see below). Although prions may be transmissible between species (in mammals or yeast), the efficiency of transmission is generally lower between species than within a species, an effect due to sequence differences between the prion proteins of the donor and recipient species. Barriers are also seen within a single species (“intraspecies barriers”) as a result of sequence polymorphisms, probably selected in the wild to reduce the probability of being infected with a pathologic prion. The ease with which any of these transmission barriers are overcome is sharply dependent on the prion variant, with some completely unable to be transmitted and others transmitted without apparent barrier. It is proposed that these barriers reflect the range of conformers that a given molecule can assume. If the donor conformer is such that the recipient can assume that structure, then there will be little barrier, and the contrary.

The genetics of prion variants makes it clear that some variants are “dominant” to others when introduced together, while other variants are compatible and segregate relative to each other during mitotic growth. While a variant may appear to be stable with respect to one property, it may be unstable with respect to another. Inaccurate templating may cause some prion “mutations”, while severely detrimental effects of a [URE3] or [PSI +] prion on the cells may lead to selection during growth of very rare milder variants or loss of the prion.

Prion Variant Information Templating Mechanism

The folded in-register parallel β -sheet architecture of the infectious yeast prion amyloids determines the structure except for the extent of the β -sheets and the location of the folds in the sheet. The structure is kept in-register by favorable interactions among identical amino acid side chains that can only happen if register is maintained (Fig. 3). This naturally suggests a mechanism by which protein conformation can be templated. In order that their amino acid side chains have these favorable interactions, the unstructured prion domains of the monomers about to join the end of the filament must have their turns at the same locations as those of the molecules already in the filament. This directs the conformation of the new molecule to be essentially that of the rest of the molecules in the filament. Each prion variant is suggested to have the folds of the sheet (=turns of the molecule) in places specific for that variant. This is the only mechanism that has yet been proposed for prion variant propagation/conformational templating.

Chaperones and Prions

Chaperones of the Hsp40, Hsp70, and Hsp104 groups, as well as Hsp90 and its co-chaperones, have been found to be clearly involved in prion propagation (Table 2). Millimolar concentrations of guanidine cure each of the amyloid-based prions by specific inhibition of Hsp104. At least one function of these chaperones is to break large amyloid filaments into smaller ones which can then be distributed at cell division. Overexpressed Hsp104 has a second activity, in curing the [PSI +] prion, and less efficiently, [URE3]. The mechanism of curing is controversial but may involve asymmetric segregation of prion filaments, possibly related to Hsp104's role in collecting damaged proteins and retaining them in the mother cell. This second Hsp104 activity is lost in mutants in (or deletion of) the N-terminal domain (e.g., T160M), but such mutants retain their prion propagation promoting activity and their ability to protect cells from heat shock. Other proteins affecting prion propagation include the nucleotide exchange factors for Hsp70s, namely Fes1p and Sse1p, the cytoskeleton assembly factor Sla1p, and the co-chaperone Sgt2p.

Prion Generation, and [PIN]: A Prion That Gives Rise to Prions

One of the lines of evidence that showed [PSI] was a prion of Sup35p was that overproduction of Sup35p increased the frequency with which [PSI] arises de novo. However, it was found that in some strains, overproduction of Sup35p did not yield detectable emergence of [PSI]-carrying clones. Another nonchromosomal genetic element, named [PIN] for [PSI]-inducibility, was found necessary. [PIN] is a self-propagating amyloid form of the Rnq1 (rich in Asn (N) and Gln (Q)) protein, and it promotes de novo generation of [URE3] as well as [PSI].

Table 2 Interactions of prions with chaperones and other proteins

Mechanism	Components	Yeast prions affected
Filament breakage: removal of a single prion protein molecule from middle of the filament generates new filaments	Hsp104, Hsp70 (Ssa1–4), Hsp40 (Sis1)	All amyloid-based prions
Filament collection ~ Asymmetric segregation	Hsp104 overproduction curing [with Hsp90s and Hsp90 co-chaperones]	[PSI ⁺], ([URE3])
?Blocking filament ends	Btn2 [with Hsp42]	[URE3], (some [PSI ⁺])
?Competition for monomers	Upf1,2,3	[PSI ⁺]
?Occupation of unstructured (prion) domains	Upf1,2,3	[PSI ⁺]
	??	??any amyloid-based prion protein
Solubilizing monomers: a consequence of the “Filament breakage” mechanism above	Hsp104, Hsp70 (Ssa1–4), Hsp40 (Sis1)	All amyloid-based prions
?Blockage of access to filaments for breakage	Excess Hsp104	[PSI ⁺]
?Sequestration of Sis1p	Cur1p overproduction	[URE3]

Biological Roles of Prions: A Help or a Hindrance?

In an attempt to discern whether yeast prions are an advantage or disadvantage to their host organism, cell growth of isogenic [PSI⁺] and [psi⁻] strains have been carried out under a variety of conditions. To what extent the various growth conditions tested represent the normal yeast habitat seems unknowable, although [psi⁻] was an advantage under far more conditions than was [PSI⁺].

An alternative approach was to compare the frequency with which [PSI⁺] or [URE3] was found in wild strains to those of several “selfish” RNA and DNA viruses and replicons known in *S. cerevisiae*. In any organism, an infectious element (such as a virus) may be widely distributed in spite of it causing disease in its host because the infection process overcomes and outraces the loss of infected individuals from the negative effects of the infecting element. Certainly an advantageous infectious element will quickly become widespread as selection and infection operate in the same direction. In fact, while the mildly deleterious RNA and DNA viruses and plasmids of yeast are easily found in wild strains neither [URE3] nor [PSI⁺] was found in any of the 70 wild strains examined. This indicates that the mildest variants of [URE3] and [PSI⁺] produce disease in their hosts, and a rather more severe disease than the mild nucleic acid replicons.

However, more detrimental variants of each prion, either dramatically slowing growth or even killing the host, are more common than the mild variants usually used for laboratory studies. Moreover, the recent discovery of an array of cellular anti-prion systems (see below) indicates that the cells themselves do not regard these prions as beneficial.

The [Het-s] prion of *Podospora* appears to carry out the normal fungal function of heterokaryon incompatibility, thought to be a protection against the sometimes debilitating fungal viruses. Indeed, as one would expect for a prion with a function for the cell, over 90% of wild *Podospora* isolates carry [Het-s], confirming its beneficial effects.

Unlike [PSI⁺] and [URE3], [PIN⁺] is found in wild strains at a frequency similar to that of the parasitic RNA and DNA viruses and plasmids. This suggests that [PIN⁺] is at least not as severe a pathogen as are [URE3] and [PSI⁺].

Anti-Prion Systems

The pathological character of yeast prions suggested that there may be cellular systems that cure prions as they arise, much as DNA repair systems eliminate most mutations as they arise. Indeed, it was found that over 90% of [URE3] variants arising (at increased frequency) in a *btn2 cur1* strain are cured by replacing just the normal amount of these proteins. Btn2p cures [URE3] by collecting Ure2p amyloid filaments at one locus in the cell, increasing the likelihood that one of the daughter cells will lack filaments and thus be cured. Likewise, the frequency of [PSI⁺] arising spontaneously is elevated over 10-fold in a mutant (T160M) that lacks the Hsp104-overproduction-curing activity toward [PSI⁺], and most of those variants are cured by just replacing the normal Hsp104 without overproduction. Mutants in the *UPF* genes, responsible for nonsense-mediated decay, show > 10-fold elevated frequency of [PSI⁺] generation, and, again, most of the variants arising are cured by restoring normal levels of expression of these proteins. Sub3p forms a complex with Upf1p, Upf2p and Upf3p, and it is suggested that this complex either competes with the filaments for free monomers, or blocks the ends of filaments preventing their growth.

The ribosome-associated Hsp70 family chaperones Ssb1p and Ssb2p keep down the frequency of [PSI⁺] arising de novo, but in this case restoring the normal amounts of these proteins does not cure the variants arising. It is inferred that the Ssbs, known to be involved in promoting proper folding of nascent proteins, prevent the generation of [PSI⁺].

The Hsp40 family member Sis1p is essential for propagation of [PSI⁺] and [URE3], but also protects cells from the potential lethality of [PSI⁺] without curing the prion. Similarly, the Lug1/Ylr352w protein prevents the near-lethality of [URE3], apparently via a novel function of Ure2p (not nitrogen regulation) that is essential in the absence of Lug1/Ylr352w.

Inositol Polyphosphates and Prion Propagation

In a screen for anti-prion systems, it was found that nearly all variants of the [PSI⁺] prion require one of several inositol poly/pyrophosphates for their propagation. Inositol hexakisphosphate (IP₆), 5-diphospho-IP₅ and 5-diphospho-IP₄ are each able to support [PSI⁺] propagation. In the absence of the 5-diphospho-IPs, the 1-diphospho-IP₅ has an inhibitory effect on [PSI⁺] propagation. Siw14p, a 5-pyrophosphatase active on 5-diphospho IPs, prevents propagation of about half of [PSI⁺] variants because they need elevated levels of that compound. The mediators of these effects are, as yet, unknown.

Enzyme as Prion

While most of the known prions involve amyloids, the word prion (infectious protein) is more general, requiring only that transmission be by protein alone. If an enzyme is made as an inactive precursor that needs the active form of the same enzyme for its activation, then such a protein can be a prion. The vacuolar protease B (Prb1p) of *S. cerevisiae* can be such a prion in a mutant lacking protease A, which normally activates its precursor. Cells initially carrying only the inactive precursor remain so unless the active enzyme is introduced. Once a cell has some active enzyme, the autoactivation process can continue indefinitely. It is likely that other examples of this type of phenomenon will be found among the many protein kinases, methylases, acetylases, and other protein-modifying enzymes that are known.

Conclusions

The advent of yeast prions has propelled the prion field forward, giving the first proof that an infectious protein can exist, the first structure/architecture of a prion amyloid, and a wide array of information on cellular components favoring and antagonizing prion propagation. With the findings that the common human amyloidosis are actually prions, the continuing insights into the general prion phenomena that are being provided by the yeast and fungal work will continue to push this field forward.

Glossary

Biological control A method to prevent pests using beneficial organisms, here specifically means using mycovirus to control fungal diseases.

DNA mycovirus, also called fungal DNA virus A DNA virus that replicates in fungi.

Gemonoviridae A group of small circular single-stranded DNA viruses that are phylogenetically related to plant geminiviruses, but lack move protein genes.

Hypovirulence Reduced virulence of a fungal pathogen caused by the infection of mycovirus; Hypovirulence and hypovirus of chestnut blight/*Cryphonectria parasitica*

system is a classic example for studying mycovirus and biological control of plant fungal diseases.

Sclerotinia sclerotiorum An worldwide spread ascomycetous fungal pathogen that can attack more than 400 species and subspecies of plants. Important disease caused by it includes stem rot on rapeseed (*Brassica napus*).
ssDNA mycovirus single-stranded DNA mycovirus.

Vegetative incompatibility A non-self-recognition system that is determined by *vic* genes in fungi, and is a mechanism for fungi to prevent the infection by molecular parasites, such as mycovirus. It is a key hindrance to successful biological of fungal diseases using mycovirus.

Introduction

DNA viruses are viruses that have DNA genomes and replicate using DNA-dependent DNA polymerase. DNA viruses can be grouped into two classes, double-stranded (ds) DNA viruses and single-stranded (ss) DNA viruses. DNA viruses are very common in both prokaryotic microorganisms and eucaryotic organisms including humans, animals, and plants. The most feared DNA viruses is variola virus which causes smallpox. Three families of DNA viruses have been established in plants, namely *Caulimoviridae*, *Geminiviridae*, and *Nanoviridae*, whereas DNA virus has been very rarely reported in fungi. Previously, a DNA virus named *Rhizidiomyces virus* was discovered in filamentous microorganism *Rhizidiomyces* sp., which used to be grouped in the kingdom Fungi, however, *Rhizidiomyces* is actually a fungi-like water mold that belongs to the kingdom Chromista. In the 1980s, a DNA virus with large virions has been observed in a strain of *Rhizoctonia solani* in China, but this study has not been followed. The presence or absence of DNA virus in fungi was unknown for a considerable period of time. In 2010, a small molecule circular single-stranded DNA virus was discovered and reported in a cosmopolitan necrotrophic pathogenic fungus *Sclerotinia sclerotiorum*. The discovery of DNA mycoviruses has significantly enriched the understanding of mycoviruses, broadened the research field of mycoviruses, and provided new research ideas and methods for the use of mycoviruses to control fungal diseases.

The Host of the DNA Mycovirus

Sclerotinia sclerotiorum is an ascomycetous plant pathogenic fungus that was firstly described in 1837 by Libert, M.A. and named *Peziza sclerotiorum*; the name was changed as *Sclerotinia libertiana* by Fuckel, L. in 1870, finally changed as the current name by de Bary, A. in 1884. *S. sclerotiorum* is a typical necrotrophic plant pathogen; it attacks more than 400 species and subspecies of plants, most of which are dicotyledons, including many economically important crops, such as cruciferous crops, leguminous crops, and compositae vegetable crops. The diseases caused by *S. sclerotiorum* are often called white mold on many vegetable crops or stem rot on rapeseed (*Brassica napus*). *S. sclerotiorum* infects plants via either ascospores or infectious hyphae, produces sclerotia on plant residues at the late stage of infection and uses them to undergo dormancy in the field. When contacting hosts, sclerotia germinate carpogenically to release ascospores into the air and infect aerial parts of plants, or germinate myceliogenically to produce infectious hyphae to infect basal stem and old leaves that contact the ground. The sclerotia, apothecia, ascuses, and ascospores, and the induced symptom on rapeseed are presented in Fig. 1. The stem rot is the major disease on rapeseed worldwide, and no resistant cultivar is available. The control of stem rot is mainly dependent on fungicides which usually is not efficient. Hence, a number of field-collected isolates of *S. sclerotiorum* were screened for hypovirulence-associated mycoviruses to control stem rot, and *Sclerotinia sclerotiorum* hypovirulence-associated DNA virus 1 (SsHADV-1) was discovered.

Discovery of DNA Mycoviruses

Sclerotia collected from rapeseed fields in China were used to screen hypovirulence-associated mycoviruses and one abnormal strain DT-8 was isolated from a sclerotium sampled at Datong Lake District, Yiyang City, Hunan Province, China. Strain DT-8 grows slowly on potato dextrose agar (PDA) medium and forms an abnormal colony morphology rich in aerial hyphae on PDA

Fig. 1 *Sclerotinia sclerotiorum* and the induced stem rot of rapeseed (*Brassica napus*). A, Sclerotia (arrows) produced on residue of dead rapeseed; B, Apothecia, germinated from sclerotia; C–D, asco and ascospores; E, Symptom on stem (arrows); F, Symptom on stem basal (arrows); G, Premature and lodging, heavy infected rapeseed field, only green plants were not killed.

plate (Fig. 2(A) and (D)). The sclerotia produced by strain DT-8 are usually smaller than these produced by normal strains of *S. sclerotiorum* and are distributed on colony irregularly (Fig. 2(C)). Only very few sclerotia could produce apothecia and ascospores, while ascospore-derived offsprings are fully recovered with no different from the normal strains; occasionally, subcultures derived from hyphal tip of strain DT-8, such as strain DT-8VF, also shows normal phenotype of *S. sclerotiorum*. Strain DT-8 almost loses virulence both on rapeseed and *Arabidopsis thaliana* (Fig. 2(B)). When extracting DNA from strain DT-8 using CTAB method, besides genomic DNA band, two or more additional small DNA bands could be observed under UV light when separated by agarose gel electrophoresis (Fig. 3(A)), while cultures cured did not have these DNA bands, suggesting that these additional DNA were possibly associated with the abnormal characteristics of strain DT-8. The additional DNA was recovered from agarose gel for sequencing analysis, and results showed that the DNA was actually a genome of a small single-stranded circular DNA virus. Isometric particles with a diameter of 22 nm (Fig. 3(C)) were successfully extracted and purified from mycelia of strain DT-8 by ultra-centrifugation, and viral DNA could be successfully extracted from virions (Fig. 3(E)). These results directly confirmed that strain DT-8 was infected by a DNA virus. By dual culture, hypovirulence and the associated traits were co-transmitted with DNA through hyphal contact (hyphal anastomosis). Furthermore purified virions could successfully transfect the protoplast of normal strain of *S. sclerotiorum*, and confer hypovirulence to its host. Hence, the DNA virus is associated with hypovirulence and named as *Sclerotinia sclerotiorum* hypovirulence-associated DNA 1 (SsHADV-1).

The Genome and Proteins of SsHADV-1

The genome of SsHADV-1 is a single-stranded circular DNA with a full length of 2166 nt (Fig. 3(B) and (F)). The genome has only two large open reading frames (ORF) encoding a coat protein (CP) with 312 amino acid residues (aa) and a putative replication initiation protein (Rep) with 324 aa. The CP gene is located on the sense strand of the DNA genome, while the Rep gene is located on the antisense strand of the DNA genome (Fig. 3(F)). The two genes are separated by two non-coding DNA, the large one called the large intergenic region (LIR) which has 133 nt, and the small one called small intergenic region (SIR) with a length of 119 nt. LIR has the nonanucleotide TAATATT ↓ AT at the apex of a stem-loop structure, which is a conserve recognition site (↓) circular ssDNA viruses for Rep to initiate viral DNA replication. Furthermore, there is a bidirectional promoter in the LIR to transcribe CP gene and Rep gene. The coat protein was confirmed by sequencing analysis of protein samples extracted from purified virions,

Fig. 2 Abnormal phenotype of strain DT-8 of *Sclerotinia sclerotiorum*. A, Abnormal colony morphology, developed on PDA medium plate at 20°C for 15 days; B, Hypovirulence, could not induce typical lesion on leaf of *Arabidopsis thaliana*, inoculated plants were maintained at 20°C for 4 days post inoculation; C, Small sclerotia produced on a PDA medium (20°C for 30 days); D, Slow growth, bars represent standard deviation from the mean ($n = 8$), the small letters on top of the bars indicate whether the differences are statistically significant ($P < 0.05$). The hypovirulent strain Ep-1PN which is infected by two RNA viruses, its virus-free sexual progeny Ep-1PNA367 and virus-free isogenic strain DT-8VF derived by hyphal tipping culture of strain DT-8 were used as controls. Reproduced from Yu, X., Li, B., Jiang, D., *et al.*, 2010. A geminivirus-related DNA mycovirus that confers hypovirulence to a plant pathogenic fungus. *Proceedings of the National Academy of Sciences of the United States of America* 107, 8387–8392.

while Rep protein was confirmed by alignment analysis with related viruses. Rep of SsHADV-1 shows high similarity to the Rep proteins of geminiviruses that infect numerous plants. Two conserved domains in the Rep proteins of geminiviruses, namely Rep catalytic domain (Gemini_AL1) (pfam00799) and Rep central domain (Gemini_AL1_M) (pfam08283) are also identified on the Rep of SsHADV-1. Seven conserved motifs which are shared with viruses in the genus *Mastrevirus* in the family *Geminiviridae* are also identified, namely IRD, RCR-I, RCR-II, RCR-III, RBR, NTP Binding-A, and NTP binding-B (Fig. 4(B)).

Host Range of SsHADV-1

SsHADV-1 can infect strains of *S. sclerotiorum* by hyphal anamostosis or just by contacting with colonies of virus-infected strains and non-infected strains. A transfection method has shown SsHADV-1 to be introduced and replicate in species in the genus *Sclerotinia*, such as *S. minor* and *S. nivalis*. However, SsHADV-1 could not replicate in *Botrytis cinerea* which belong to the same family as *Sclerotinia* sp. SsHADV-1 also could neither replicate in *Coniothyrium minitans*, a mycoparasite of *Sclerotinia* spp., *Magnaporthe oryzae* nor *Saccharomyces cerevisiae* which are phylogenetically distant to its natural hosts. As far as we know, there is no any report that SsHADV-1 could infect other fungi in nature. Hence, SsHADV-1 has a narrow fungal host range.

Extracellular Entry of SsHADV-1

Many mycoviruses have no significant effects on their host, and often lack extracellular phase, hence are also considered to be dispensable genetic elements in fungi. Virions of mycoviruses generally are not able to infect their host directly. Unlike most known mycoviruses, SsHADV-1 can infect *S. sclerotiorum* through intact hyphae. When colonies of virus-free strain of *S. sclerotiorum* contacts SsHADV-1 virions which are spread on a PDA plate, the virus enters into fungal cells and successfully infect the colony and convert hypovirulence to the virus-free strain (Fig. 5(A)–(C)). The virions also can infect *S. sclerotiorum* on plants, when sprayed

Fig. 3 Genomic structure and virions of *Sclerotinia sclerotiorum* hypovirulence-associated DNA virus 1 (SsHADV-1). A, Extrachromosomal DNA elements in strain DT-8 DNA samples were extracted with CTAB method from mycelia of strain DT-8. DNA samples were separated on 1.0% agarose gel. Lane Marker 1, λ -Hind III-digested DNA Marker; Lane Marker 2, DL2000 DNA ladder marker (TaKaRa). B, Southern blot analysis of total DNA extracted from mycelia. The forms of viral DNA are indicated as “OC dsDNA” for open circular double-stranded (ds)DNA, “SC” dsDNA for supercoiled dsDNA, and “circular” for circular single-stranded (ss) DNA. A 379-bp DNA fragment of the Rep gene was PCR amplified and labeled with α - 32 P dCTP and used as a probe. C, Isometric virions (about 22 nm) purified from mycelia of strain DT-8, observed under transmission electron microscopy. Virions were negatively stained with 1% uranyl acetate before observation. D, The major protein (coat protein) of SsHADV-1 extracted from virions separated by SDS/PAGE. Virions were extracted from mycelial mass of strain DT-8 and purified by ultra-centrifugation. The protein was stained with Coomassie blue before observation. E, Viral genomic DNA extracted from virions separated on 1% agarose gel. F, Genome structure of SsHADV-1. Two large Open Reading Frame (ORFs), one coding for coat protein (CP) and one for putative replication initiation protein (Rep) were presented as thick arrows. The positions of the conserved stem-loop structure for small circular single-stranded DNA viruses, large intergenic region (LIR) and small intergenic region (SIR) were displayed; the detail DNA sequence of stem-loop structure was also shown on the right. LIR is also shown in an expanded form to indicate the elements of the bidirectional promoter. Reproduced from Yu, X., Li, B., Jiang, D., *et al.*, 2010. A geminivirus-related DNA mycovirus that confers hypovirulence to a plant pathogenic fungus. *Proceedings of the National Academy of Sciences of the United States of America* 107, 8387–8392.

on the aerial parts of plant (Fig. 5(D)–(E)); however, virions on plant are not stable and will be disabled in a short time after sprayed on plants. These properties suggest that SsHADV-1 has a potential to biological control of plant diseases.

Mutualistic Interaction Between SsHADV 1 and Mushroom Sciarid Fly

Mushroom sciarid fly *Lycoriella ingenua* (Diptera: Sciaridae) is a common pest in mushroom houses (Fig. 6(A)). A phenomenon is that SsHADV-1-infected strain DT-8 always specifically attract sciarid fly to lay eggs on its colony, and the larva feeds on the colony and

Fig. 4 Conserved domains and motifs on putative Rep of SsHADV-1. A, The locations of two conserved domains, Gemini_AL1 and Gemini_AL1_M are geminivirus Rep catalytic domain (accession no. pfam00799) and geminivirus Pep protein central domain (pfam08283), the E-values are 1.77e-12 and 5.01e-08. This schematic is automatically generated by the Blastp program on NCBI when using Rep of SsHADV-1 as a query sequence. B, Alignment analysis of amino acid sequences among SsHADV-1 and selected viruses from the genus *Mastrevirus* in the family *Geminiviridae* by using CLUSTALX (2.0). Identical and similar amino acid residues are indicated with asterisks and colons. Conserved motifs I to VII are IRD, RCR-I, RCR-II, RCR-III, RBR, NTP Binding-A, and NTP binding-B are shaded with light gray color. "TbYDV" means tobacco yellow dwarf virus (NP_620726), "CpCDV" means chickpea chlorotic dwarf virus (YP_002014712) and "BeYDV" means bean yellow dwarf virus (NP_612221); numbers in brackets are the positions of amino acid residues that are not listed. Reproduced from Yu, X., Li, B., Jiang, D., et al., 2010. A geminivirus-related DNA mycovirus that confers hypovirulence to a plant pathogenic fungus. *Proceedings of the National Academy of Sciences of the United States of America* 107, 8387–8392.

eats out all hyphae (Fig. 6(B)). After feeding on colony of the virus-infected strain, the insect develops to pupa from larva, and then adult emerges from pupa, after mating, female adult then lays eggs back to the fungal colonies. Viral DNA of SsHADV-1 could be determined by PCR amplification from the larva, pupa, adults (female and male), and eggs of fly that was fed on virus-infected colonies (Fig. 6(C)–(E)), suggesting that this fly carries hyphae attaching on insect surface or in the gastrointestinal system, or that SsHADV-1 enters into insect cells. The insects fed on a virus-infected colony were further examined using immunofluorescence observation with the antibody of coat protein, and results showed that strong fluorescence signal could be observed in the head of larva and pupa, in the digestive tract and oviduct of adults and in eggs (Fig. 6(F)–(I)). These observations suggest that SsHADV-1 enters into tissues and cells of sciarid fly, and replicates in this insect. The virions of SsHADV-1 was used to challenge the cells of *Spodoptera frugiperda* (Sf9), and SsHADV-1 was examined by passage experiment, RT-PCR amplification, Flow cytometry analysis, Northern blot analysis, and immunofluorescence observation under confocal microscope (Fig. 6(K) and (L)). These assays demonstrated that SsHADV-1 could replicate in Sf9 cells and in sciarid fly.

To understand why the virus-infected colony could attract sciarid fly, the volatile compounds released by both virus-infected and virus-free colonies were collected and analyzed with GC–MS. The results showed that virus-infection suppresses the biosynthesis of 1-Octen-3-ol and 3-Octanone, and "Y" shape tube test revealed that high concentrations of these two compounds are likely to be repellents for adults of sciarid fly. The fecundity of female adults can be significantly increased when larvae are fed on the virus-infected colony. This result suggests that SsHADV-1 modifies the secondary metabolites of *S. sclerotiorum*.

Transmission of SsHADV-1

Mycoviruses are often transmitted vertically by host's reproduction, mostly by host asexual reproduction, occasionally by both asexual and sexual reproduction, and also transmitted horizontally by hyphal anastomosis between virus-infected and virus-free strains. Horizontal transmission of mycoviruses is usually suppressed by a fungal vegetative incompatibility system, hence virus cannot efficiently transmit between two vegetative incompatible strains. SsHADV-1 cannot transmit vertically since *S. sclerotiorum* does not form any asexual spores, while sclerotia cannot germinate easily to form apothecia, and ascospore-offsprings are virus-free. Unlike other mycoviruses, SsHADV-1 can transmit between two vegetative incompatible strains (Fig. 7). The possible mechanism is that virions of SsHADV-1 can infect hyphae of *S. sclerotiorum* directly via an extracellular route. While growing, hyphae of virus-infected strain frequently break and tear so that virions are easily released. When hyphae of virus-free strain contact

Fig. 5 SsHADV-1 directly infects intact hyphae of *Sclerotinia sclerotiorum* and protects plants against *S. sclerotiorum*. A–C, Purified virions infect hyphae on PDA medium. A, Sectoring observed in a colony of a virus-free strain Ep-1PNA367 at 2 dpi. Strain Ep-1PNA367 grew on a PDA plate for 1 day and then virions were spread on the PDA medium around the margin of the young colony with a distance of about 1–2 cm. PBS buffer was used instead of virion suspension as a control, no sectoring was observed in the colony. The photographs were shot at 4 dpi; B, Abnormal colony morphology of SsHADV-1-infected strain Ep-1PNA367, colony morphology of strain Ep-1PNA367 and strain DT-8 were also presented. All cultures were incubated on PDA medium for 7 d at 20°C; C, Viral DNA could be extracted from infected strain Ep-1PNA367 and observed by agarose gel electrophoresis. Lane M: λ -Hind III digested DNA Marker. Lanes 1–3, DNA samples of strains Ep-1PNA367, virus-infected Ep-PNA367, and DT-8, respectively. D–E, Spraying virions of SsHADV-1 protects plants against the infection of *S. sclerotiorum*. D, Virions suspension prevented *S. sclerotiorum* from killing plants of *A. thaliana*. Virions suspensions at different concentrations were spread on one leaf of each plant, and then mycelial agar disks from the merge of active colony of strain Ep-1PNA367 were placed on the treated leaves. The inoculated plants were maintained in an incubator with 100% relative humidity (RH) at 20°C, and photographs were shot at 6 dpi. E, Therapeutic activity of virions against the attack of *S. sclerotiorum*. Virion crude suspension inhibited the expansion of *S. sclerotiorum* on rapeseed plants and cured the lesions. *S. sclerotiorum* were pre-inoculated on plant leaves for 2 days for lesion development, and then virions suspension, chemical fungicide Carbendazim (100 ppm) or PBS buffer was sprayed on plants. Three leaves were inoculated for each plant. Plants were maintained in an incubator with 100% RH at 20°C, and photographs were shot at 8 and 12 dpi. Reproduced from Yu, X., Li, B., Fu, Y., *et al.*, 2013. Extracellular transmission of a DNA mycovirus and its use as a natural fungicide. *Proceedings of the National Academy of Sciences of the United States of America* 110, 1452–1457.

virions, infection happens. Although transmission vectors of RNA mycoviruses have not been discovered yet, SsHADV-1 can replicate in sciarid fly and enter into eggs, suggesting that sciarid fly can possibly transmit SsHADV-1. Viruliferous larva, pupa, adults, and eggs (acquired virus by feeding on virus-infected colony) and larvae and pupae which are injected with purified virions could transmit virus to virus-free fungal strains. The transmission also occurs on rapeseed plants (Fig. 8), suggesting that SsHADV-1 and sciarid fly undergo a mutualistic lifestyle in the field.

Distribution of SsHADV-1

It is most likely that SsHADV-1 is widely distributed. Firstly, SsHADV-1 has been observed in strains of *S. sclerotiorum* isolated from many places in China; Secondly, it also has been detected in Australia strains of *S. sclerotiorum*; Thirdly, viral DNA of SsHADV-1 has been detected in the river sewage in New Zealand. Additionally, viral DNA of SsHADV-1 is detected in dragonflies (*Pantala hymenaea*). Different viral strains in the same species as SsHADV-1 (qcv23688.1) were also found in Haddock in the United States, with Rep identity of 78% (253/324) and similarity of 83% (272/324). These findings indicate that the distribution of SsHADV-1 is worldwide, at least in Asia, North America, and Oceania.

Lane M, DNA marker; Lane 1, DNA sample from strain DT-8; Lanes 2–5, DNA samples from larvae starved for 1, 3, 5, and 7 d, respectively; Lane 6, DNA sample from larvae reared on strain DT-8VF. F–J, Immunofluorescence detection of SsHADV-1 in larva, pupa, midgut, and midgut of female adults, and eggs of *L. ingenua*. Insect developed either on the colony of strain DT-8 (a) or on the colony of strain DT-8VF (b) (negative control) was used for detection. F, Larvae, longitudinal section of larvae (head parts); G, Pupae, longitudinal section of pupae (head parts); H, Midgut of female adults. Photographs shown at the upper right were magnified from a part of midgut (indicated by red boxes); I, Ovarian duct of female adults; J, Eggs dissected from female adults. Bars at the bottom right are 200 μ m for F and G, 100 μ m for H, I, and J, 50 μ m for the upper right in H. Samples were stained with secondary antibody FITC conjugated to virions-specific monoclonal antibody prepared with viral CP protein. The Immunofluorescence reaction was observed under a confocal microscope (fv1000mp, Olympus). K and L, SsHADV-1 replicates in Sf9 cells. K, Immunofluorescence examination of SsHADV-1 in Sf9 cells, cells were inoculated with SsHADV-1 virions and observed at 72 hpi bars = 20 μ m. L, Northern blot analysis for expression of viral Rep and CP gene in Sf9 cells. DIG-labeled DNA probes of 853 bp and 901 bp corresponding to viral DNA for Rep and CP gene, respectively, were used. Reproduced from Yu, X., Li, B., Jiang, D., *et al.*, 2010. A geminivirus-related DNA mycovirus that confers hypovirulence to a plant pathogenic fungus. *Proceedings of the National Academy of Sciences of the United States of America* 107, 8387–8392.

The Taxonomy of SsHADV-1

SsHADV-1 is phylogenetically closely related to geminiviruses that infect numerous plants, the Rep protein of SsHADV-1 showed high similarity to these of viruses in the family *Geminiviridae*. However, the coat protein gene is different from these of viruses in family *Geminiviridae*. Hence, SsHADV-1 should have some evolutionary relation with geminiviruses, but also significantly different from these viruses. In 2012, a novel genus *Gemycircularvirus*, a name from Gemini-like myco-infecting circular virus was established with SsHADV-1

Fig. 7 SsHADV-1 transmits between two vegetative incompatible strains of *S. sclerotiorum*. A and B, Incompatible reaction (cell death zone, red arrow indicated) between a hygromycin-resistant strain Ep-1PNA367R (a) and strain DT-8VF (b) or its isogenic strain DT-8 (c). For A, colonies were dual cultured on a PDA plate for one week. Photograph was shot from the reverse side of the plate, for B, strain DT-8 was inoculated 2 days ahead of inoculation of strain Ep-1PNA367R on a PDA plate, the photograph was taken at 7 days post inoculation of strain Ep-1PNA367R. C, Both strain Ep-1PNA367R and SsHADV-1-infected strain Ep-1PNA367R (d) derived from dual culture in B could grow on hygromycin-amended PDA medium (50 μ g/mL), while strains DT-8 and DT-8VF could not. Both strain DT-8 and SsHADV-1-infected strain Ep-1PNA367R were developed in plate for 4 d, while strain Ep-1PNA367R and strain DT-8VF for one day. D-G, SsHADV-1-infected strain Ep-1PNA367R conferred hypovirulence and its associated trait to strain Ep-1PNA367R by dual cultivation. D, Colony morphology of strain Ep-1PNA367R changed after contacting with the SsHADV-1-infected strain Ep-1PNA367R, which is different from strain Ep-1PNA367R (E), but similar to virus-infected one (F); Colonies in the dual culture were developed for 10 days for virus-infected strain, and for 7 days for strain Ep-1PNA367R, colonies for E and F were developed on PDA medium for 7 d. G, SsHADV-1-infected strain Ep-1PNA367R lost virulence on *Arabidopsis* (d). H, Viral DNA was extracted in newly infected strain Ep-1PNA367R. Lane M, λ -Hind III digested DNA Marker; Lane 1, newly infected strain Ep-1PNA367R; Lane 2, Ep-1PNA367R; Lane 3, strain DT-8. Reproduced from Liu, S., Xie, J., Cheng, J., *et al.*, 2016. DNA mycovirus infects a mycophagous insect and utilizes it as a transmission vector. *Proceedings of the National Academy of Sciences of the United States of America* 113, 12803–12808.

as the exemplar virus. In 2016, a new family, *Genomoviridae* (sigil: Ge- for geminivirus-like, nomo- for no movement protein) was established with SsHADV-1 representative virus strain of the type species, *Sclerotinia gemycircularvirus 1*, in the genus *Gemycircularvirus*. In *Gemycircularvirus*, there are more than 43 sister species reported from the world at different niches. These gemycircularviruses are associated with plants, animal tissues (including humans, mammals, birds, insects, sea fish, and reptile, etc.), and feces of mammals and birds, sewage and sediments and waste water. However, only SsHADV-1 is well-studied, the others are only viral sequences, and their exactly hosts are not known. Based on the complete amino acid sequence of Rep of SsHADV-1 and other selected viruses, a phylogenetic

Fig. 8 Transmission of SsHADV-1 by mushroom sciarid fly on rapeseed plants. A, Rapeseed plants were inoculated with strains DT-8 (left) and 1980 (right) with a 30 cm distance between two basins. The basin was sealed and kept 100% RH and then virus-free larvae were placed on small lesions induced by strain DT-8. When right side plants were killed by strain 1980, subcultures recovered from diseased plant residues were subjected to virus detection; B, PCR-positive subcultures (AT1, AT7, and AT10) were confirmed with Southern blot analysis with the same probe used in Fig. 6(D). Viral DNA for Southern blot analysis was amplified with rolling circle amplification (RCA); DNA samples extracted from strains DT-8 and 1980 were used as controls. C-F, Colony morphology, growth rate, sclerotial production and virulence of virus-infected subcultures AT1, AT7, and AT10 were significantly different from that of virus-free strain 1980. Reproduced from Liu, S., Xie, J., Cheng, J., *et al.*, 2016. DNA mycovirus infects a mycophagous insect and utilizes it as a transmission vector. *Proceedings of the National Academy of Sciences of the United States of America* 113, 12803–12808.

tree was constructed using Maximum Likelihood method with a MEG 7.0 program. From the evolutionary tree, viruses in the *Gemycircularvirus* and its-related genera in the family *Genomoviridae* are extremely rich in diversity (Fig. 9).

Explore SsHADV-1 to Control Fungal Disease

The history of using hypovirulence-associated mycovirus to control fungal disease can date back to the early 1970s of the last century. At that time, a transmissible hypovirulent strain was isolated from self-cured cankers caused by the chestnut blight fungus (*Cryphonectria parasitica*), and this hypovirulent strain was successfully used to control chestnut blight in European countries. It became evident later that the transmissible hypovirulent strain was actually caused by the infection of mycovirus (*Cryphonectria hypovirus 1*). This successful example prompted a large number of phytopathologists to screening for similar hypovirulence-associated mycoviruses in different pathogenic fungi and expected to be applied in different fungal disease systems. Unfortunately, these studies have not achieved significant success, even for the hypovirus, the control efficiency of chestnut blight in the United States is not satisfactory. The common consensus is that the efficient transmission of mycoviruses is limited by the host vegetative incompatibility system (also called non-self-recognition system). Mycoviruses can only spread efficiently among host individuals in the same vegetative compatible group, but cannot move in different vegetative compatible groups. Fungi usually have complicated vegetative incompatibility system, making use of mycoviruses to control diseases almost impossible. Of course, a group of scholars have made continuous efforts to overcome this difficulty, which will make it possible to control chestnut blight with hypovirus in the near future.

Unlike most known viruses, SsHADV-1 has very unique characteristics. First, the vegetative incompatibility could not prevent the efficient spread of SsHADV-1 in the population of *S. sclerotiorum*; second, SsHADV-1 can drive insect as transmission vectors, which may help SsHADV-1 spread in the field in a short time; third, virions of SsHADV-1 can directly infect hyphae of *S. sclerotiorum*, that

makes it possible to use virus particles or processed virus particles to control *Sclerotinia* disease. Field experiment demonstrated that spraying hyphal fragment suspension of SsHADV-1-infected strain DT-8 on rapeseed plants at the blossom stage could also reduce disease severity and enhance rapeseed yield up to 16.4% under field conditions. SsHADV-1 and strain DT-8 were introduced to the United States in 2017 by Prof. Weidong Chen in Washington State University for investigating its potential on biological control of white mold of leguminous crops caused by *S. sclerotiorum*.

Introduction

Double-stranded RNA (dsRNA) viruses infect practically all organisms, from bacteria to unicellular and/or multicellular simple eukaryotes (fungi, protozoa), through to plants and animals. Although dsRNA viruses are a rather diverse group, they share general architectural principles and numerous functional features. The complexity of the capsid ranges from single shell to multilayered and concentric capsid. Whereas the outer shell has a protective role and is involved in cell entry, the innermost capsid (or inner core) is devoted to the organization of the viral genome and viral polymerase. This inner capsid consists of 120 protein subunits arranged in a T=1 icosahedral shell, i.e., a capsid protein (CP) dimer is the asymmetric unit. The T=1 capsid is also referred to as a “T=2 layer” – an exception to the quasi-equivalence theory introduced by Caspar and Klug.

The T=1 capsids of dsRNA viruses are critical for genome replication (minus-strand synthesis) and transcription (plus-strand synthesis), with the viral RNA-dependent RNA polymerase(s) (RdRp) frequently packaged as an integral component of the capsid. T=1 capsids also function as molecular sieves, allowing the exit of positive single-stranded RNA transcripts for protein synthesis, and the entrance of nucleotides for intra-capsid RNA synthesis. The pores are presumably small enough to exclude potentially degradative enzymes. In addition, T=1 capsid remains structurally undisturbed throughout the viral cycle, isolating dsRNA molecules and any replicative intermediates, thus preventing the triggering of dsRNA sensor-mediated antiviral host defense mechanisms such as RNA silencing, interferon synthesis and apoptosis.

The totiviruses *Saccharomyces cerevisiae* virus L-A (ScV-L-A) and *Ustilago maydis* virus H1 (UmV-H1), which infect the yeast *Saccharomyces cerevisiae* and the smut fungus *Ustilago maydis*, respectively, were the first unambiguously described viruses with a T=1 capsid formed by 12 decamers (rather than 12 pentamers). The conservation of this stoichiometry and architecture is probably related to the stringent requirements of capsid RNA metabolism-associated activity (the capsid organizes the packaged genome and the replicative complex[es]).

T=1 120-subunit capsids have been described for members of the *Reo-* and *Picobirnaviridae*, which mostly infect higher eukaryotic organisms. They have also been described for bacteriophages of the family *Cystoviridae* that infect the prokaryote *Pseudomonas syringae*. These capsids are also present in members of the *Toti-*, *Partiti-*, *Megabirna-*, *Chryso-*, and *Quadriviridae* families, that largely infect unicellular and/or multicellular simple eukaryotes such as fungi, protozoa, but also some plants.

In contrast with the smooth outer surface of T=1 capsid of reoviruses, the 120-subunit capsids of fungal dsRNA viruses have a corrugated outer surface with protuberances rising above the continuous protein shell. Notably, the average thickness of a 120-subunit T=1 CP is 15–30 Å in mammalian dsRNA viruses, but those of mycoviruses are thicker. Unlike their bacteria- and higher eukaryote-infecting counterparts, most mycoviruses are transmitted by cytoplasmic interchange; they never leave the host, and indeed have no strategy for entering host cells. Recent studies of fungal (and protozoan) dsRNA viruses have identified functional and structural features dissimilar to those recorded for reoviruses, as well as evolutionary relationships among T=1 capsid structural proteins. Mycovirus particles accumulate in the fungal cytoplasm; the close relationship between the fungal dsRNA virus and its host probably placed many constraints on the virus that it overcame by increasing CP complexity.

The T=1 capsid proteins of four mycoviruses have been resolved at the atomic level: Gag of the yeast virus ScV-L-A (family *Totiviridae*), CP of *Penicillium chrysogenum* virus (PcV, family *Chrysoviridae*), CP of *Penicillium stoloniferum* virus F (PsV-F, family *Partitiviridae*), and the heterodimer P2-P4 of *Rosellinia necatrix* quadrivirus 1 (RnQV1, family *Quadriviridae*).

Structure of dsRNA Virus Capsids

Totiviruses

Saccharomyces cerevisiae virus L-A is the type species of the genus *Totivirus* (family *Totiviridae*). The ScV-L-A genome is a 4.6 kbp, single-segment dsRNA molecule that encodes a major CP (termed Gag; 680 residues, 76 kDa) and the viral polymerase (Pol; 868 residues, 94 kDa) as a Gag-Pol fusion protein generated by – 1 ribosomal frameshifting (Pol is bound covalently to the inside of the particle wall).

The structure of ScV-L-A was first examined by three-dimensional cryo-electron microscopy (3D cryo-EM) and later by X-ray crystallography at a resolution of 3.4 Å. Scanning transmission electron microscopy (STEM) was used to determine the virus stoichiometry. The rough, icosahedral, ~40 nm diameter T=1 lattice of ScV-L-A has 120 copies of Gag, of which one or two are fused to the Pol moiety (Fig. 1(a) and (b)). The structural unit is an asymmetric Gag dimer. Each Gag monomer can adopt two related conformations, termed A and B, which have notable structural differences and reside in different bonding environments (i.e., make non-equivalent contacts) within

[☆]This work is dedicated to the memory of our friend and colleague, Said A. Ghabrial, who passed away in November 2018.

[†]Deceased.

Fig. 1 Structure of the ScV-L-A $T=1$ capsid and X-ray-based structure of the CP. (a) Cryo-EM image of ScV-L-A. Bar, 500 Å. (b) Cryo-EM $T=1$ capsid of ScV-L-A viewed along a twofold axis of icosahedral symmetry, showing the Gag subunits A (blue) and B (yellow). (c) Atomic model of a Gag dimer (top view; PDB accession number 1m1c). Icosahedral symmetry five- (pentagon), three- (triangle) and two-fold (oval) axes are indicated in black.

the capsid (**Fig. 1(c)**). These subunits are arranged in two sets of five: five A subunits directly surrounding the icosahedral five-fold axis, leaving an 18 Å diameter channel for the entry of nucleotide triphosphates and the exit of viral mRNA, and five B subunits intercalated between the A subunits, forming a decamer. Twelve such (A:B)₅ decamers then constitute the complete capsid. This quaternary organization is similar to the 120-subunit $T=1$ inner core of reoviruses, in which adjacent A and B subunits within each decamer are oriented approximately in parallel, suggesting an asymmetric A:B dimer as a possible intermediate for capsid assembly.

Gag functions as an enzyme and has a major role in the sophisticated interaction between ScV-L-A and the host cell. The Gag segment Gln139-Ser182 (in which His154 is the active site) contributes to the rough outer surface of the capsid, mediates decapping of cellular mRNAs and transfers the 7-methyl-GMP (m^7 GMP) cap from the 5' end of the cellular mRNA to the 5' end of the viral RNA. L-A counters a host exoribonuclease that targets uncapped RNAs (such as viral mRNA), allowing the latter to compete with host mRNA for use of the translation machinery.

Helminthosporium victoriae virus 190S (HvV190S), the prototype of the genus *Victorivirus* in the family *Totiviridae*, infects the filamentous fungus *H. victoriae*, and has a similar capsid organization to that of ScV-L-A. The smooth HvV190S capsid is composed of 120 CP monomers, with RdRp incorporated as a separate, non-fused protein. The RdRp is either non-covalently associated with the underside of the capsid (as in reoviruses), or free in the capsid interior, or non-covalently bound to the genome. 3D structures have also been reported for two protozoal members of this family, *Trichomonas vaginalis* virus 1 and *Giardia lamblia* virus, and show strong similarities to the fungal virus structures.

Chrysovirus

Chrysovirus are isometric virions characterized by a multipartite genome. *Penicillium chrysogenum* virus (PcV) is the prototype virus of the *Chrysoviridae*, a family of largely symptomless mycoviruses with a genome typically consisting of four monocistronic genome segments (genome size 2.4–3.6 kbp). Each segment is encapsidated separately in a similar particle, i.e., chrysovirus are multisegmented and multiparticulate virions. dsRNA-1 (3.6 kbp) encodes the RdRp (1117 residues, 128.5 kDa; 1 or 2 copies per virion), dsRNA-2 (3.2 kbp) encodes the CP (982 residues, 109 kDa), and dsRNA-3 and -4 (3 and 2.9 kbp, respectively) code for virion-associated proteins of unknown function (912 residues, 101 kDa and 847 residues, 95 kDa, respectively).

The 3D structures of the capsids of two chrysovirus have been determined by cryo-EM analysis, that of PcV at atomic resolution, and that of *Cryphonectria nitschkei* chrysovirus virus 1 (CnCV1) at subnanometer resolution. Stoichiometric estimates by analytical ultracentrifugation analysis indicated that PcV and CnCV1 virions are exceptions to the most extended tendency among dsRNA viruses – a $T=1$ core with 60 equivalent dimers – since they have an authentic $T=1$ capsid formed by 60 copies of a single monomer. The capsid diameter is 400 Å and the protein shell 48 Å thick (**Fig. 2(a)** and **(b)**). Similar to ScV-L-A, the outer capsid surface of PcV is relatively

Fig. 2 Cryo-EM- based structure of the PcV T=1 capsid protein. (a) Cryo-EM image of PcV. Bar, 500 Å. (b) T=1 capsid of PcV viewed along a twofold axis of icosahedral symmetry, showing the N-terminal domain A (1–498, blue), the linker segment (499–515, red), and the C-terminal domain B (516–982, yellow). (c) Top view of the atomic model of the PcV CP (3j3i; 982 residues). Symbols indicate icosahedral symmetry axes.

uneven with 12 outwardly protruding pentons (each containing five copies of the CP); this contrasts with the T=1 capsid of reoviruses, in which the CP has a plate-like structure and serve as a template to prime the assembly of the T=13 surrounding capsid. The 982-residue CP of PcV is formed by duplication of an α -helical domain; this is indicative of gene duplication despite negligible sequence similarity between the two roughly parallel α -helical domains (Fig. 2(c)). The N-terminal A domain (residues 1–498; Fig. 2(c), blue) and the C-terminal B domain (residues 516–982; Fig. 2(c); yellow) are connected by a 16-residue linker (Ala499-Ile515; Fig. 2(c), red) accessible from the capsid outer surface. These domains are arranged in two sets of five; five A domains directly surround the icosahedral fivefold axis, and five B domains intercalated between them, forming a pseudodecamer (Fig. 3(a)). This organization is clearly reminiscent of the 120-subunit T=1 lattice of totivirus capsids, in which the two asymmetrical dimer components are arranged approximately in parallel. The structural details of PcV capsid reinforce the idea that a T=1 layer with a dimer as the asymmetric unit provides an optimal framework for managing dsRNA metabolism.

Superimposition of the PcV A and B α -helical domains (Fig. 3(b) and (c)) identifies a single “hotspot” located on the capsid outer surface where variations are introduced by insertion of 50–100 residue polypeptides (Fig. 3(c), orange triangle). A preferential insertion site would allow the acquisition of new functions while preserving basic CP folding. It is plausible that, in addition to its structural role, chrysovirus CP might also have enzymatic activity, like ScV-L-A CP.

Quadriviruses

Rosellinia necatrix quadrivirus 1 (RnQV1) is the exemplar of the type species of the genus *Quadrivirus* in the family *Quadriviridae*. The filamentous ascomycete *Rosellinia necatrix*, a pathogen of many plants, can be infected by dsRNA viruses belonging to at least six families. RnQV1 is associated with latent infections and has a multipartite genome consisting of four monocistronic dsRNA segments (as in chrysoviruses) with genome sizes ranging from 3.7 to 4.9 kbp. DsRNA-1 (4.9 kbp) codes for a protein of unknown function (1602 residues), dsRNA-2 (4.3 kbp) encodes the P2 CP (1356 residues), dsRNA-3 (4 kbp) codes for RdRp (1117 residues), and dsRNA-4 (3.7 kbp) codes for the P4 CP (1061 residues).

RnQV1 strains W1075 and W1118, isolated from different locations in Japan, have been analyzed by 3D cryo-EM and analytical ultracentrifugation. Their P2 and P4 proteins co-assemble into isometric virus particles ~45 nm in diameter, that each package either one or two of the four genome segments (Fig. 4(a)). Whereas most dsRNA virus capsids are based on dimers of a single protein, RnQV1 has a single-shelled T=1 capsid formed by 60 P2 and P4 protein heterodimers (Fig. 4(b)). P2 and P4 of RnQV1 strain W1118 remain nearly intact, but in strain W1075 both proteins are cleaved into discrete polypeptides, apparently without altering capsid structural integrity. The atomic structure of the RnQV1 W1118 capsid at 3.7 Å resolution shows that P2–P4

Fig. 3 *PcV* capsid protein is a structural duplication. (a) Atomic model of the *PcV* capsid viewed along a twofold axis (color code as in Fig. 2(c)). (b) Superimposed A and B domains (white segments indicate non-superimposed regions for both domains). (c) Sequence alignment of domains A (blue) and B (yellow) resulting from Dali structural alignment. α -helices (rectangles) and β -strands (arrows) are rainbow-colored from blue (N terminus) to red (C terminus) for each domain. Triangles represent non-aligned segments (sizes indicated): the orange triangle indicates the single “hotspot” on the outer capsid surface. Strictly conserved residues are on a red background and partially conserved residues are in a red rectangle. Adapted from Luque, D., Gómez-Blanco, J., Garriga, D., *et al.*, 2014. Cryo-EM near-atomic structure of a dsrna fungal virus shows ancient structural motifs preserved in the dsRNA viral lineage. *Proceedings of the National Academy of Sciences of the United States of America* 111 (21), 7641–7646.

Fig. 4 *RnQV1* $T=1$ capsid cryo-EM-based structure. (a) Cryo-EM image of empty *RnQV1* particles. Bar, 500 Å (b) $T=1$ capsid of *RnQV1* viewed along a twofold axis of icosahedral symmetry, showing P2 (blue) and P4 (yellow). (c) Top view of the atomic models of P2 (blue) and P4 (yellow) (PDB accession number 5nd1).

heterodimers are organized into a quaternary structure similar to that of the homodimers of chrysoviruses and totiviruses (Fig. 4(c)). Although the *RnQV1* capsid, and that of *PcV*, is an exception to the rule that all dsRNA viruses have a $T=1$ capsid with a CP homodimer as the asymmetric unit, it follows the architectural principle that a 120-subunit capsid is a conserved assembly that supports dsRNA replication and organization.

Fig. 5 *PsV-F* and *RnMB1* $T=1$ capsids. (A) X-ray-based structure of the $T=1$ capsid of *PsV-F* viewed along a twofold axis of icosahedral symmetry, showing the CP subunits A (blue) and B (yellow). Bar, 100 Å. (b) Top view of the atomic model of a *PsV-F* CP dimer (3es5). Symbols indicate icosahedral symmetry axes; red oval indicates a local twofold symmetry axis. (c) Side view of a *PsV-F* CP dimer. The protruding arch (P) and shell (S) domains are indicated. (d) Cryo-EM $T=1$ capsid of *RnMB1* viewed along a twofold axis of icosahedral symmetry, showing the rough boundaries of subunits A (blue) and B (yellow). Bar, 100 Å.

Despite their low sequence similarity, the superimposition of P2 and P4 revealed them to have a common α -helical domain. As described for the *PcV* capsid protein, P2 and P4 appear to have also acquired new functions through the insertion of complex domains at preferential insertion sites on the capsid outer surface. These domains are probably related to enzyme activity. The P2 insertion has a fold similar to that of gelsolin and profilin, two actin-binding proteins with a function in cytoskeleton metabolism, whereas the P4 insertion suggests a protease activity involved in cleavage of the P2 383-residue C-terminal region (absent in the mature viral particle). This P2 C-terminal segment might represent an external scaffolding domain.

Partitiviruses

Members of the family *Partitiviridae* have bisegmented, 3.1–4.8 kbp-long genomes. Each segment is encapsidated separately in a similar virus particle. dsRNA1 encodes RdRp (1 copy per particle), while dsRNA2 encodes the CP. The partitiviruses that infect fungi are grouped into three genera: *Alpha-partitivirus*, *Beta-partitivirus*, and *Gamma-partitivirus*. Alpha- and beta-partitiviruses infect plants or filamentous fungi, whereas gamma-partitiviruses infect only the latter. In general, partitivirus infections are largely symptomless.

Four fungal partitivirus structures have been resolved by 3D cryo-EM, including those of the gamma-partitiviruses *Penicillium stoloniferum* virus S (*PsV-S*) and *Penicillium stoloniferum* virus F (*PsV-F*) (by X-ray crystallography at 3.3 Å resolution), and of the beta-partitiviruses *Fusarium poae* virus 1 (*FpV1*) and *Sclerotinia sclerotiorum* partitivirus 1 (*SsPV1*).

The single-layered, 120-subunit capsids of these viruses are 35–42 nm in diameter and distinctive in having “arch-like” surface features that protrude above the continuous capsid shell (Fig. 5(a)–(c)). These $T=1$ capsids have a different quaternary organization, their CP dimer having almost perfect local twofold symmetry (Fig. 5(b)). The quasi-symmetric CP dimer is stabilized by domain swapping within the shell region of the A and B subunits, as well as by intradimeric interactions between equivalent protruding arch domains on the particle surface (Fig. 5(c)). A similar organization has been found in a picobirnavirus, a bisegmented dsRNA virus that infects humans and other vertebrates. Based on their capsid organization, partiti- and picobirnaviruses are proposed to be assembled from dimers of CP dimers (i.e., tetramers) as intermediates. In contrast, the proposed assembly pathway for the 120-subunit capsids of *Toti-* and *Reoviridae* members is based on pentamers of CP dimers (i.e., decamers).

Megabirnaviruses

Rosellinia necatrix megabirnavirus 1 (*RnMBV1*) is the exemplar of the type species of the genus *Megabirnavirus* in the family *Megabirnaviridae*. The *RnMBV1* genome has two dsRNA segments, separately encapsidated in isometric particles of ~50 nm

diameter. dsRNA1 (8.9 kbp) encompasses two partially overlapping ORF's; ORF1 encodes the CP (135 kDa) and ORF2 codes for the RdRp, which is expressed as a fusion protein with CP (250 kDa). dsRNA2 (7.2 kbp) has two non-overlapping ORF's that encode proteins with unknown functions. RnMBV1 causes severe reduction of both mycelial growth of *Rosellinia necatrix* and fungal virulence to plant hosts, and thus has strong potential for virocontrol of white root rot.

RnMBV1 structure has been analyzed by 3D cryo-electron microscopy (Fig. 5(d)). Similar to ScV-L-A, the outer capsid surface of RnMBV1 is rough with 120 spherical large protrusions on the virus surface (~ 50 Å wide). The role of these protruding domains is unknown.

Evolutionary Relationships Based on Structural Comparisons

Structural comparisons of CPs are used to establish relatedness when sequence conservation is limited, and have detected relationships among viruses that infect organisms that, in evolutionary terms, are widely separated. Icosahedral viruses are grouped into four lineages: the dsDNA viruses with an upright double β -barrel CP (the prototypes are phage PRD1 and adenoviruses), the head-tailed phages and herpesviruses that share the Hong Kong 97 (HK97)-like CP fold (also termed the Johnson fold), the picornavirus-like superfamily with a single β -barrel as the CP fold, and the dsRNA or bluetongue virus (BTV)-like viruses. The PRD1- and HK97-like lineages include archaea-, bacteria-, and eukaryote-infecting viruses, suggesting that their last common ancestral hosts were infected by the progenitors of the current viral lineages before the host organisms diverged.

The similarity of the A and B α -helical domains of PcV CP, which have many well-matching secondary structural elements, indicate a common fold in both domains (Fig. 3). It is noteworthy that domain duplication has recently been detected in the capsid protein of other dsRNA fungal virus, botybirnaviruses. Gene duplication (or joined folds) has been a recurrent evolutionary event in other viral lineages. The conserved ~ 350 residue-long PcV fold is also preserved in the Gag of ScV-L-A (Fig. 6). This basic α -helical domain shares many secondary structural elements with ScV-L-A Gag, in particular those regions involved in interactions at the icosahedral symmetry axes. The preserved fold in Gag has three peptide insertion sites facing the outer capsid surface, one of which colocalizes with the single-insertion hotspots of the PcV CP domains. This colocalization suggests that these preferential insertion sites are ancient, and provide a means for the acquisition of new functions without altering the structural and functional motifs of the dsRNA virus CP.

P2 and P4 of RnQV1 also have a common fold some 300 residues long, with two preferential insertion sites on the outer surface. Both coincide with the ScV-L-A Gag insertion sites, and one with the single-insertion site of the PcV A and B α -helical CP domains. Notably, the conserved folds of PcV and ScV-L-A CP are similar to the common fold of P2 and P4, indicating that this fold may have evolved from a common ancestral domain of the dsRNA virus lineage (Fig. 6).

Duplication of an ancestral gene for a CP with the BTV-like fold might have resulted in two separate (as in quadriviruses) or covalently joined folds (as in chrysovirus). This event could direct assembly of a $T=1$ capsid with 120 subunits or domains with a dimer as the asymmetric unit, a necessary arrangement for dsRNA replication/transcription. Separate and joined folds are found in the CP of other virus families such as picornaviruses and comoviruses, respectively. Once the 120-subunit capsid was well established, later divergent evolutionary events would have introduced additional changes in each copy, or even the complete removal of one of them, giving a CP that assembles as a dimer of unfused identical monomers. Alternatively, the ancestral CP could have initially acquired dimer assembly ability, followed by gene duplication.

RdRp and dsRNA Organization Within Mycovirus Capsids

Reovirus $T=1$ cores have 10–12 RdRp complexes per virion, around which the dsRNA is densely coiled. RdRp complexes are non-covalently anchored to the capsid inner surface near the icosahedral five-fold axes, as presumably they are in mycoreoviruses. In addition to RdRp molecules, reovirus replicase complexes include a few minor core proteins with ATPase and/or RNA binding activities. For members of the *Toti*-, *Chryso-Partiti*-, and *Quadriviridae* families, the RdRp molecules are incorporated into 1 or 2 copies per particle, and show more variability than reovirus. For chryso-, partiti- and quadriviruses, the RdRp is expressed as a physically separate protein from a discrete genome segment, and is incorporated into virions via non-covalent interactions with the capsid and/or genome. The same is true for victoriviruses such as HsV190S, except that the RdRp is expressed from the single genome segment of those viruses. For totiviruses such as ScV-L-A, in contrast, the RdRp is expressed as a C-terminal fusion product with the CP. As a result, in ScV-L-A, the 1 or 2 RdRp domains per virion are covalently tethered to the capsid via the fused CP domain, which occupy 1 or 2 subunit positions in the capsid.

The mycovirus $T=1$ capsid wall is perforated by many channels, but none is large enough to pass an A-form 23-Å-diameter genomic dsRNA. Thus the capsid functions as a molecular sieve. Whereas the largest pores (15–20 Å diameter and usually located near the fivefold axis) would allow the passage of nascent mRNA into the host cytoplasm, the smallest holes (5–10 Å in diameter and usually located at the three-fold axis) could be used for nucleotide substrate or pyrophosphate byproduct diffusion. In non-transcribing $T=1$ capsids, the pores are very narrow, but the N- or C-termini or the side chains of residues that face the channel wall might adopt alternative conformations to allow the exit of viral transcripts.

Fig. 6 Structural homology of mycovirus *T=1* CP. The PcV CP A domain (PcV-A, left, center) was structurally aligned with ScV-L-A Gag (right, center), and P2 (top, center) and P4 (bottom, center) with PcV-A and ScV-L-A Gag. Center rainbow-colored structures indicate conserved secondary structure elements within the dsRNA viruses. PcV-A is aligned with ScV-L-A Gag (blue and pink, center). P2 is aligned with PcV-A (blue and light blue, top left) and with ScV-L-A Gag (blue and pink, top right). P4 is aligned with PcV-A (yellow and blue, bottom left) and P4 with ScV-L-A Gag (yellow and pink). Total numbers of secondary structural elements with close relative spatial locations are indicated. Reproduced from Luque, D., Mata, C.P., Nobuhiro, S., Ghabrial, S.A., Castón, J.R., 2018. Capsid structure of dsRNA fungal viruses. *Viruses* 10 (9), 481.

With the exception of totiviruses (which have a single genomic segment), many fungal dsRNA viruses, including chryso-, partiti-, and quadriviruses, have multisegmented dsRNA genomes. In addition, the multisegmented viruses appear to be multiparticulate, i.e., segments are encapsidated separately. Fungal dsRNA viruses have spacious capsids compared to the inner cores of complex eukaryotic dsRNA viruses (Table 1). Whereas reoviruses have 9–12 dsRNA genomic segments packed into liquid crystalline arrays at high density (~ 40 bp/100 nm³ – a spacing between dsRNA strands of 25–30 Å), fungal virus capsids (including ScV-L-A, PcV, PsV-F and RnQV1) contain a single, loosely packed dsRNA molecule (~ 20 bp/100 nm³ – an interstrand spacing of ~ 40 –45 Å). In reoviruses, individual genome segments must be transported through the active sites of the RdRp complexes at the 5-fold axes, and template motion could be a limiting factor. ScV-L-A is a simplified version of these viruses, with a single-segment genome. The looser packing of the dsRNA would probably improve template motion in the more spacious transcriptional and replicative active particles, minimizing electrostatic repulsion between dsRNA strands.

Most mycovirus *T=1* capsids are negatively charged on their inner surface, a feature common to many such capsids of dsRNA viruses. This might facilitate the movement of template and/or product RNA molecules by repulsion, maintaining the RNA layer at ~ 25 Å from the capsid surface (Fig. 7(a), (c), and (d)). The PcV capsid is an exception. It has positively charged regions on the inner

Table 1 Genome packaging densities in fungal dsRNA viruses

Virus family	dsRNA features			Capsid features		
	No segments	Size (kbp)	MW ^a (MDa)	CP (residue)	ϕ^b/ir^c (nm)	dsRNA density (bp/100nm ³) ^d

Fig. 7 dsRNA virus $T=1$ capsid inner surfaces with electrostatic potentials. (a)–(d) ScV-L-A (a), PcV (b), PsV-F (c), and RnQV1 (d) capsid inner surfaces viewed along a twofold axis of icosahedral symmetry. The inner surface charge representations of these capsids show the distribution of negative (red) and positive (blue) charges. Note the numerous electropositive areas in PcV. dsRNA and packaged proteins (such as RNA polymerases) were removed computationally.

surface (Fig. 7(b)), and shows numerous interactions with the underlying genome, which is ordered in the outermost RNA layer. As a result, there is almost no space between the latter layer and the inner capsid surface. These contacts have been defined at the atomic level in PcV and PsV-F virions. The lower density of the central region and the associated slight increase in dsRNA mobility might be necessary for maximum RdRp activity in the context of a non-fused RdRp complex.

Comparative analysis of dsRNA packing densities in dsRNA virions have revealed two major tendencies among $T=1$ capsids of dsRNA viruses: (1) those with 9–12 dsRNA segments densely packaged within the same particle and containing 9–12 RdRp complexes, as seen in reoviruses, and (2) those with a single-genomic dsRNA segment with less internal order and one or two copies of the RdRp complex per particle, as seen in mycoviruses.

Concluding Remarks and Future Perspectives

Structural studies of a limited number of fungal viruses have revealed them to hold to the basic concepts of dsRNA viruses, but also to have unexpected features that have contributed to a better understanding of their structure, function, and evolution. dsRNA mycovirus capsids, exemplified by ScV-L-A, PcV, PsV-F, and RnQV1, show structural variations of the same framework optimized for RNA metabolism; they possess 60 asymmetric or symmetric dimers of a single protein (as in ScV-L-A or PsV-F, respectively), dimers of similar domains (as in PcV), or dimers of two different proteins (as in RnQV1). Since mycoviruses are commonly confined to their hosts, their capsids incorporate polypeptides and domains on their outer surfaces for the acquisition of new functions without altering the structure and function of the CP. Such acquisitions would eventually lead to optimal viral-host interactions.

Despite the recent advances made in understanding the structure of dsRNA mycoviruses, many aspects of many fungal viruses remain unknown. Future structural studies should focus on the asymmetric substructures and components of their capsids – such as their RdRp (isolated or packaged inside virions) – and their packaged dsRNA genome.

Ustilago maydis Viruses and Their Killer Toxins

Alexis Williams and Thomas J Smith, The University of Texas Medical Branch, Galveston, TX, United States

© 2021 Elsevier Ltd. All rights reserved.

This is an update of J. Bruenn, *Ustilago Maydis* Viruses, In *Encyclopedia of Virology* (Third Edition), edited by Brian W.J. Mahy and Marc H.V. Van Regenmortel, Elsevier Ltd., 2008, doi:10.1016/B978-012374410-4.00519-7.

The Totiviruses

The family *Totiviridae* comprises dsRNA viruses that are classified in five genera; *Totivirus*, *Victorivirus*, *Giardiavirus*, *Leishmanivirus*, and *Trichomonasvirus*. Members of the genera *Giardiavirus*, *Leishmanivirus*, and *Trichomonasvirus* infect protozoa, whereas totiviruses and victoriviruses infect fungi. Only giardiaviruses and trichomonasviruses make capsids that are released from the host to infect other cells. The other members of the family persistently infect their hosts and never leave the cytoplasm.

The word 'toti' is Latin for 'whole' and reflects the fact that the genome is undivided. The positive strand of the genome has two overlapping open reading frames; the coat protein (gag) followed by the polymerase (pol). A fraction of the gag/pol proteins are fused together via a translational frameshift. Even for those genera that do not leave the host, the capsid acts to sequester the dsRNA genome away from the antiviral cellular machinery and form a 'mini nuclei' for genome replication. Early cryo-EM image reconstructions of two representatives of the genus *Totivirus*, *Ustilago maydis* virus H1 (UmV-H1) and *Saccharomyces cerevisiae* virus L-A (ScV-L-A) showed that the capsids have an unusual $T = 1$ icosahedral symmetry where two identical copies of the gag protein are in each icosahedral asymmetric unit. While $T = 2$ is not an acceptable icosahedral triangulation number, these capsids have been called ' $T = 2$ ' to reflect this unusual capsid architecture. These structures were subsequently followed by a crystallographic structure of ScV-L-A, shown in Fig. 1. Structures of several members of the totivirus family have now been determined and are reviewed in the recent paper describing the structure of the giardiavirus, *Giardia lamblia* virus strain Portland I (GLV-I). In spite of low sequence similarity, all members of the family *Totiviridae* share this unusual ' $T = 2$ ' symmetry.

The production of the gag-pol fusion protein plays a critical role in ScV-L-A and UmV-H1 viral replication. In ScV-L-A, there are approximately two copies of the fusion protein per virion where the capsid protein portion forms part of the capsid and the RNA dependent RNA polymerase lies inside the capsid where genome replication occurs. For the toxin encoding species, additional dsRNA segments are separately encapsidated. These are essentially satellite dsRNAs and wholly dependent upon the main portion of the viral genome for their replication and coat protein.

The Killer Phenomena

Several strains of *Ustilago maydis*, a causal agent of corn smut disease, exhibit a 'killer' phenotype that is due to persistent infection by *U. maydis* viruses. These viruses produce potent killer proteins that are secreted by the host. This is a rare example of virus/host symbiosis in that these viruses are dependent upon host survival and, to that end, produce antifungal proteins that kill competing, uninfected strains of *U. maydis*.

Three killer strains of *U. maydis* have been characterized to date: P1, P4 and P6, that secrete KP1, KP4 and KP6 toxins, respectively. Correspondingly, there are three groups of resistant cells where resistance is determined by three independent recessive nuclear genes: p1r, p4r and p6r. The identities of these resistance factors are unknown. These factors are specific for each antifungal protein. Therefore, there are no single resistance alleles that confer simultaneous resistance to all three toxins. All three immunity genes are recessive to their sensitive alleles. Immunity factors are not conferred by the viral genome itself. Resistance to these antifungal proteins was found in ~20% of haploid strains in the natural population. The incidence of strains expressing a toxin is ~1% of the total population and is close to the expected frequency if immunity is a recessive, nuclear encoded factor. This implies that the viruses and their hosts have undergone a co-evolutionary process where the viruses incorporated antifungal proteins, perhaps from other fungi in the distant past, and immunity factors in the host have been selected for that protect it from the effects of the antifungal proteins.

KP4

The KP4 toxin is different from the other *U. maydis* killer proteins. It is a single polypeptide of 105 amino acids and, unlike KP1 and KP6, is not processed by Kex2p protease. There is no significant sequence similarity between KP4, KP6, and other known toxins. While most of the yeast toxins are acidic and the KP6 and KP1 toxins have neutral pI's, KP4 is extremely basic with a pI > 9.0. The structure of KP4 has a unique, compact α/β sandwich structure held together by five disulfide bonds (Fig. 2). α/β proteins are very common and the majority function by interacting with other proteins. KP4 has a single split $\beta\alpha\beta$ motif with a total of seven β -strands

Fig. 1 Structure of the ScVL1 capsid. Subunits A and B are shown here in red and blue, respectively. Ribbon diagrams of one copy of A and B are also shown in this “T = 2” particles. This unusual capsid organization was also found in UmV and other members of the totivirus family. The 2, 3 and 5-fold axes of symmetry are indicated.

Fig. 2 Atomic structure of KP4. This ribbon diagram is colored red to blue as the chain extends from the N to the C termini. The five disulfide bonds are represented by ball and stick models. Also shown is lysine 42 (K42) which, when mutated to a glutamine or chemically modified abrogates KP4 activity.

(131–137) and three α -helices ($\alpha 1$ – $\alpha 3$). One of the most unusual features of the protein is that the two major helices, $\alpha 2$ and $\alpha 3$, have a left-handed $\beta\alpha\beta$ cross-over conformation. The possible biological function of these unusual arrangements is unclear. It may be to create a more hydrophobic ‘cup-like’ surface on the opposite side of the β -sheet that might be important for protein-protein interactions.

Effects of KP4 on *U. maydis* Cells

The dogma had been that KP4 affects *U. maydis* cells by forming pores in the cell membrane like colicin and some of the small anti-microbial peptides found in animals and yeast. However, from its structure this seemed unlikely. KP4 is only 105 residues in length but contains 5 disulfide bonds and is highly charged. From this, it seemed unlikely that it would form channels on its own or, because of the disulfide bonds, be able to undergo the kinds of conformational changes required to form pores in the membrane. The structure of KP4 is moderately similar to that of scorpion alpha toxins, which are known to target voltage gated sodium channels and inhibit growth in susceptible cells. Therefore, it was proposed KP4 inhibits growth of susceptible fungi through targeting a membrane surface ion channel. To test for this, cell growth was measured in the presence of KP4 with increasing concentrations of K^+ , Na^+ , Mg^{2+} , and Ca^{2+} . Ca^{2+} was very effective at abrogating KP4 inhibition, but, with the exception of a slight effect by K^+ , none of the other metals had any effect even at very high concentrations. This suggested that KP4 might be blocking Ca^{2+} channels. If true, then this further suggests that the block is via reversible protein-protein interactions with the Ca^{2+} channels. To test this hypothesis, sensitive P2 cells were treated for more than 24 h with high concentrations of KP4 and then extensively washed with minimal media. When treated in this way, the cells did recover with about a 6-h delay. Ca^{2+} added to the

wash was very effective at removing all KP4 inhibition. This suggests that Ca^{2+} abrogates KP4 effects by directly blocking toxin binding.

In scorpion toxin AaHII, K58 is a highly reactive lysine and lies near the C-terminus that, when chemically modified, inactivates the toxin. To test whether KP4 and scorpion toxins share this critical feature, KP4 was mutated and chemically modified. There is only one lysine in KP4, K42 (Fig. 2). As with scorpion toxin, when this lysine was chemically modified with acetic anhydride there was a total loss in KP4 activity. This result was confirmed with site directed mutagenesis where K42 was replaced with a glutamine and was also found to block KP4 activity. Finally, as a direct proof that KP4 blocks metal ion import, we demonstrated that KP4 inhibited uptake of $^{45}\text{Ca}^{2+}$ in *U. maydis* cells. Subsequently, experiments were performed with animal cells where electrophysiology is more tractable without the cell wall and the various types of Ca^{2+} channels are well characterized.

KP4 Blocks L-type Voltage Gated Ca^{2+} Channels

The most convincing evidence that KP4 acts on Ca^{2+} channels was that KP4 specifically blocks voltage gated animal channels. KP4 blocked $\text{Ca}_v1.2$, but had no effect on $\text{Ca}_v2.1$ or $\text{Ca}_v2.3$ channels. KP4 specifically blocks L-type Ca^{2+} channels with a weak voltage dependence to the block. In a manner akin to the calciseptine peptide block of $\text{Ca}_v1.2$, KP4 does not affect the voltage-dependence of activation but slightly shifts the voltage-dependence of inactivation of the channel. KP4 activity against both mammalian and fungal cells was blocked by chemical modification of the single lysine residue – akin to what was found with scorpion toxin. Further, as was observed in fungi, the inhibition of the animal $\text{Ca}_v1.2$ channel was abrogated by the addition of Ca^{2+} . Interestingly, we suggested at the time that calcium channel protein (Cch1) was the likely target for KP4 since Cch1 showed homology to the mammalian voltage gated L-type Ca^{2+} channels.

Effect of KP4 on Plants

Since KP4 affects fungal and mammalian calcium influx, it was important to ascertain what effect it might have on plants. Unlike in mammalian cells, calcium ion channels are not as selective in plants when it comes to transporting divalent and monovalent charged ions. A plant homologue of L-type mammalian channels is the *rca*/VDCC2 channel. This channel responds to changes in membrane potential similar to the range of L-type calcium channels, is sensitive to inhibition by dihydropyridine (DHP) derivatives, and has similar calcium ion conductance as their mammalian counterparts.

To measure possible effects of KP4 on plant calcium channels, a non-intrusive and real-time method was chosen to monitor the effects of these antifungal proteins on tip-growing root hair cells. A transgenic line of *A. thaliana* expressing an enhanced yellow fluorescent protein/Rab GTPase fusion protein, EYFP-RabA4b, was used to monitor calcium gradients. RabA4b is involved in a vesicular transport and is localized to the tips of growing root hairs but disappears in mature root hair cells that have stopped expanding. As in fungal hyphae, the root hair tip growth is associated with an apex-high cytosolic free calcium gradient generated by a local influx of calcium at the tip. This calcium gradient was shown to be crucial for RabA4b localization since disruption of the calcium gradient causes a concomitant abrogation of the RabA4b gradient.

The addition of KP4 to growing root hairs causes rapid dissipation of the EYFP-RabA4b gradient at the apical tip and a concomitant cessation of root hair elongation. In all cases, the EYFP-RabA4b gradient was reestablished and root hair extension resumed after KP4 was washed away. Consistent with KP4 blocking a calcium influx channel, the speed of this KP4 effect, and subsequent removal, suggests it targets the outer membrane where it can rapidly bind and cause its effects. Consistent with these results, growth of whole roots was also inhibited by the exogenous application of KP4 and this effect is also blocked by the addition of exogenous calcium. Therefore, KP4 is targeting some conserved portion of calcium channels that are conserved among three kingdoms.

Possible Application of KP4: Fungal Resistance in Plants

Maize smut is a global disease responsible for extensive agricultural losses. In spite of the apparent inhibitory effect of adding KP4 exogenously to *Arabidopsis* root hairs, we created several lines of transgenic maize to see whether constitutive expression of KP4 would confer resistance to *U. maydis* infection. To target KP4 to the extracellular space of transgenic maize, a monocot codon-optimized KP4 gene containing the secretory signal peptide sequence of a plant defensin MsDef1 was placed under the control of a constitutive maize *Ubi1* promoter. KP4 was expressed to high levels *in-planta* as per ELISA and killing assays without any apparent impact on plant development. The fact that we did not see any phenotypic effect of KP4 on root development could be due to less sensitivity of transgenic maize roots to KP4, possible adaptation of the plants to KP4 expression, or that the local concentration of KP4 around the roots is significantly lower than in the experiments described above.

Since transgenic maize lines secreted bioactive KP4 protein, we next determined the ability of this protein to protect transgenic lines from the corn smut disease. Transgenic maize lines expressing KP4 were made and compared to control lines. Seven-day-old seedlings were inoculated with a mixture of the wild-type *U. maydis* KP4-sensitive strains. Both strains generated galls in

nontransgenic maize plants. When the transgenic plants were challenged with *U. maydis* by stem or ear inoculation, they exhibited robust resistance in a dose-dependent manner. These results demonstrate that this family of naturally expressed antifungal proteins holds promise in identifying new targets for antifungal agents and a novel means to protect crops against fungal infections. While KP4 does affect fungi other than *U. maydis* (e.g., *Fusarium graminearum* and *Aspergillus fumigatus* (Smith and Shah, unpublished results)), there has to be strong activity against pathogens of commercial importance. Future studies on the structure/function of KP4 may improve activity against these more commercially important pathogens.

Evolutionary Origin of KP4

Recently, a large number of KP4-like genes/proteins were found in plants and fungi other than *U. maydis*, including the secretome of *Fusarium graminearum*. From sequence analysis, it appears that KP4 likely evolved in a progenitor fungus, possibly a Sordariomycete, and then moved by horizontal gene transfer to other organisms including *U. maydis*. However, it was not clear what function these KP4-like proteins might serve in these pathogenic fungi. Recent studies demonstrated that three KP4-like genes in *F. graminearum* are up-regulated as the fungal infection progresses in wheat. However, it is not clear whether this is causation or just correlation. Interestingly, calcium signaling plays a major role in a wide range of physiological responses in the plant upon fungal infection including cytoskeletal and reactive oxygen species response. It is tempting to speculate that perhaps the original fungus expressing KP4 used it to dampen plant cellular defenses against infection. Consistent with this is the fact that the effects of KP4 on *U. maydis* are abrogated by exogenously adding cAMP, an important secondary messenger for calcium signaling, to the media. It may be that, unlike the channel forming toxins, KP4 evolved to disrupt cytoplasmic signaling pathways regulated by cytoplasmic calcium gradients.

KP6

KP6 is translated as a single polypeptide chain and processed by Kex2p during export through Golgi apparatus to form α and β subunits by the elimination of a 31-residue linker region. There is relatively little known about how KP6 affects *U. maydis* cells. Previous studies have eliminated possible chitinase or protease activity and it is clear that it acts in a manner wholly different to that of KP4. While 100 mM CaCl_2 completely blocks KP4 inhibition and as little as 20 mM CaCl_2 is sufficient to cause significant abrogation, none of the metals had any significant effect on the KP6 killing of *U. maydis* (Smith, unpublished data). The only published data on the mode of action of KP6 suggested that it might be having a strong effect on the membrane integrity or osmotic regulation.

KP6 needs both subunits for activity. Both subunits can be expressed separately in immune *U. maydis* cells and become active when mixed together. Sensitive *U. maydis* cells are able to produce KP6 α but not KP6 β . This suggests that KP6 β added to the extracellular media is not toxic but is when expressed intracellularly. Sensitive *U. maydis* cells can be treated with KP6 α alone without any evidence of antifungal affects. However, if the sensitive cells are killed when treated with KP6 α alone, washed, and then KP6 β is added. However, if sensitive cells are treated with KP6 β , washed, and then KP6 α is added, there is no antifungal activity. Together, this suggests that KP6 α may bring KP6 β into the cell for killing.

The Atomic Structure of KP6

KP6 α forms a single domain structure that has an overall ellipsoid shape and also belongs to the α/β -sandwich family (Fig. 3). The tertiary structure consists of a four-stranded antiparallel β -sheet, a pair of antiparallel α -helices, a short strand along one edge of the sheet, and a short N-terminal helix. Although the fold is reminiscent of toxins of similar size, the topology of KP6 α is distinctly different in that the α/β -sandwich motif has two right-handed $\beta\alpha\beta$ split crossovers. Interestingly, the two KP6 subunits are nearly identical (Fig. 3). The RMSD of the 3D alignment using Chimera was 1.5 Å using 74 of the residues in each of the subunits. Within each subunit, the N and C termini are in close proximity. However, in the $\alpha\beta$ heterodimer, the C terminus of KP6 α is on the opposite side of the N-terminus of KP6 β (Fig. 3). From modeling studies of what the protoxin structure might look like, it seems likely that the $\alpha\beta$ heterodimer undergoes a major structural transition, perhaps activation, during Kex2p processing and export.

This N-terminal region is where the majority of the differences lie between KP6 α and KP6 β (Fig. 3). In KP6 α , there is an amphipathic α -helix at the N-terminus whereas in KP6 β , the N-terminus is shorter by five residues and is entirely a coil structure with the first three residues disordered. In KP6 β , the $\beta 3\text{-}\alpha 3$ loop is much longer than that in KP6 α and lies in the general region of this N-terminal α -helix in KP6 α . The only other major difference is that the $\alpha 2\text{-}\beta 2$ loop is longer and partially disordered in KP6 β .

The α -helix at the N-terminus of the α -subunit is rather unusual in that a disulfide bond holds it in a position that presents a very hydrophobic surface to the aqueous environment rather than burying it within the protein (arrows in Fig. 3). Interestingly, in the structure of KP6 α alone, this hydrophobic patch forms trimeric interactions in the crystal lattice. Clearly there is strong pressure to bury this helix, away from the aqueous environment. It seems likely that this hydrophobic region plays an important role in targeting the fungal cell, perhaps the cell membrane or a membrane associated protein.

Fig. 3 Atomic structure of KP6. Top: Shown here are the atomic structures of the α and β chains of KP6. The colors of the models change from blue to red as the chains extend from the N to the C termini. The disulfide bonds are represented as ball and stick models. Note the hydrophobic, exposed, phenylalanine residues at the N-terminal helix of the α chain. Bottom: Stereo diagram showing the high degree of structural homology between the α and β chains of KP6. The α chain is colored as a rainbow as in the top figure while the β chain is mauve colored. Note that the core structures of the two subunits are nearly identical and most of the differences are found in the N-termini.

KP1

Relatively little is known about the structure and mode of action of KP1. KP1 is secreted by the P1 *U. maydis* strain, is 12.9 kDa in size, is not glycosylated, and has a basic pI of 8.0. Similar to KP6, KP1 is produced as a pre-protoxin and then processed by Kex2p cleavage to produce two polypeptides, KP1 α and KP1 β . However, unlike KP6, that requires both polypeptides for killing, KP1 only requires the β subunit. Just as KP4 and both KP6 polypeptides, KP1 contains six cysteine residues, all of which are probably connected via disulfide bonds. To date, the structure, the cellular receptor, the mechanism of killing, and the ED₅₀ of KP1 remain unknown.

Comparison of the Killer Proteins

As discussed above, while KP4 and KP6 are both expressed by *U. maydis* viruses, they share no homology with regard to structure or function. For comparison, Fig. 4 shows schematic diagrams for KP1, KP4, KP6, and yeast toxin, K1. From the structures of KP4 and KP6, the disulfide bond pattern is represented by grey lines while the locations of cysteine residues are represented by yellow balls in the KP1 and K1 sequences. At the bottom are the results of transmembrane helical predictions based on the various sequences.

The general organization and sizes of KP6, KP1, and K1 pre-protoxins appear comparable (Fig. 4). However, there is no significant sequence similarity among any of them. Using a transmembrane prediction algorithm, TMHMM2, a very interesting pattern appears among the toxins. As expected, all four toxins are predicted to have transmembrane helices in the N-terminal export signal. For KP1, KP4, and KP6, this is the only part of the protein predicted to have a transmembrane helix. In contrast, there are predicted to be two additional transmembrane helices in the α subunit of K1. This is consistent with the results suggesting that the α subunit of K1 affects the membrane integrity of the target cell. While not shown in the figure, those helices are also predicted to be in the *S. cerevisiae* toxins K2 and K28. This suggests that the *S. cerevisiae* toxins interact with the target in a homologous manner with each other, while the *U. maydis* toxins are quite different among themselves as well as the *S. cerevisiae* toxins.

The other significant difference among the toxins are the disulfide bond patterns and locations of cysteine residues. KP4 is the only single subunit toxin and has five disulfide bonds in the 105 residues. Similarly, both subunits of KP6 are heavily stabilized by disulfide bonds with four and three disulfide bonds in the α and β subunits, respectively. This is important to deduce mode of action since these disulfide bonds make it impossible for the proteins to undergo large conformational changes that could form pores in the membrane like colicin. Therefore, in solution, these are stable hydrophilic proteins that seem more likely to interact

Fig. 4 Similarities and differences among the fungal toxins. In these scaled diagrams of the pre-protoxins, the various regions of the proteins are represented by the various colors. The mauve and orange arrows highlight the signal peptidase and Kex2p protease cleavage sites, respectively. The grey lines in the KP4 and KP6 figures represent the disulfide bonds observed in the crystal structure. For the other diagrams, the locations of cysteine residues are highlighted in yellow. The bottom figure shows the results of the transmembrane helix prediction algorithm, TMHMM2. Note that KP1, KP4, and KP6 only have predicted transmembrane helices in the signal peptide while K1 has two additional predicted helices in the α subunit.

with cell membrane proteins than form channels in the hydrophobic membrane. In the absence of a crystal structure, the disulfide bonding pattern of KP1 is less clear but there are sufficient cysteine residues to make 2–3 disulfide bonds in the two subunits. K1 has three cysteine residues in each subunit with at least one from each forming an inter-subunit disulfide link. Interestingly, the cysteine residues in the α subunit are clustered between the two predicted transmembrane proteins. Therefore, the *S. cerevisiae* toxins appear to be more flexible by virtue of fewer, if any, intra subunit disulfide bonds and more likely to interact with the membrane via the trans membrane helices.

Glossary

Anastomosis Fusion of somatic hyphae followed by exchange of cytoplasmic contents.

Horizontal transmission The transmission of virus, parasite, or other pathogens from one individual to another within the same generation.

Innate immunity Physical and chemical barriers including cells, cytokines, and antiviral proteins that inhibit infection

with little specificity and without generation or adaptation of a protective memory.

NLRs A class of cytosolic nucleotide oligomerization domain (NOD)-like receptors that recognize non-self signals in plants, animals, and fungi.

Vegetative incompatibility A self/non-self recognition system in filamentous fungi that determines the outcome of hyphal fusion between fungal individuals.

Introduction

Self and non-self recognition widely exist among all organisms, which include the immune systems in vertebrates, self-incompatibility during reproduction in plants, mating and vegetative incompatibility (VI) in fungi. Non-self recognition determines the outcome of somatic fusion between different tissues and causes conflicts between individuals that belong to different genetic backgrounds. In filamentous fungi, fungal colony with an interconnected network are formed via hyphal tips extension and branching formation. Different fungal isolates can undergo hyphal fusion to form a heterokaryon, and this process is essential for cytoplasmic communication and sexual reproduction in fungi. If two fungal individuals have one or more different *het/vic* loci, the fusion cells commonly show vacuolization and PCD reaction. Therefore, hyphal contact between two incompatible fungal individuals usually results in a macroscopic phenotype with black-pigmented bands (death cells) at the interface between two contacting fungal isolates, while isolates with the same genetic background can be well integrated and form one colony.

Vegetative compatibility groups (VCGs) are defined as compatible isolates that have the same *het/vic* loci and genetically related within the same species. Isolates from different VCGs differ in colony phenotype and pathogenicity among some fungi, such as *Rhizoctonia solani*. Therefore, VCGs identification is a useful tool to analysis fungal population structure and evaluate the evolution of invasive pathogen fungi, such as *Hymenoscyphus fraxineus* and *Ophiostoma novo-ulmi*. In *Aspergillus flavus*, toxigenic and atoxigenic isolates belong to different VCGs, and atoxigenic VCGs can be used as biocontrol agents to reduce aflatoxin content by increasing the incidence of the atoxigenic isolates among natural population. The application of atoxigenic VCGs supplied an important biocontrol strategy for plant pathogens.

The capable transmission of intracellular parasites among fungal individuals under natural condition is an essential factor for spreading infectious diseases. Mycoviruses as a group of intracellular parasites, are considered to be limited to intracellular transmission, with the exception for *Sclerotinia sclerotiorum* hypovirulence-associated DNA virus 1 (SsHADV-1) which has an extracellular phase. Mycoviruses can spread effectively within a fungal colony or between different strains that belong to the same fungal VCGs. In black *Aspergilli*, *C. parasitica*, and *S. sclerotiorum*, somatic incompatibility can efficiently block virus transfer among vegetatively incompatible individuals. Therefore, VI can effectively reduce the risk of horizontal transmission of mycovirus and its related genotypes among fungal populations.

Heterokaryosis is believed to be controlled by the function of *het* genes in fungi. So far, *het* genes have been cloned in some model species that include eleven *het* loci in *Neurospora crassa*, nine *het* loci in *Podospora anserina*, eight *het* loci in *Aspergillus nidulans* and six *het* loci in *C. parasitica*. Furthermore, the interaction between horizontal transmission of CHV1 (Cryphonectria hypovirus 1) and *vic* systems in *C. parasitica* has been thoroughly studied. Horizontal transmission of virulence attenuating CHV1 is known to be restricted by VI systems. In *C. parasitica*, two super mycovirus donor strains (SD328/SD82) were generated by disrupting four out of six *vic* genes, and a mixture of these two strains can delivery CHV1 to different VCGs both in the laboratory and under natural conditions. In *S. sclerotiorum*, *Sclerotinia sclerotiorum* mycoreovirus 4 (SsMYRV4) could help heterologous viruses to transmission among different VCGs via inhibiting VI-mediated PCD of donor strains. The feature of SsMYRV4 also creates a bridge strain for viruses spreading between different VCGs under natural conditions. These results demonstrated that the biocontrol capability of hypovirulent-associated mycoviruses can be enhanced via modifying the vegetative compatibility type among fungal populations.

In this article, we focus on the process of hyphal fusion between individuals from different VCGs. We analyze the genetic and molecular control of VI reactions. We also examine the ubiquitous immune system of NLRs to analyze the role of HET proteins in processing PCD and mycovirus transmission upon allorecognition in filamentous fungi. These analyses will provide clues for enhancing mycovirus horizontal transmission via block/weaken VI reactions in fungi.

Fig. 1 Cell fusions between *S. sclerotiorum* isolates. (A) Cell fusion between vegetatively compatible and vegetatively incompatible isolates of *S. sclerotiorum*. Strains were cultured on PDA medium supplemented with 75 μ L/L of McCormick's red food coloring for 48 h. Strains Ep-1PNA367 and RL6 belong to the same VCG, while strains RL19, 1980, RL26 and RL29 are from different VCGs. A clear line separates the individual strains that are vegetatively incompatible. (B) Light microscope observation of cell fusion between vegetatively compatible isolates (left panel) and vegetatively incompatible isolates (right panel). (C) SEM observation of the cell fusion (left panel: vegetatively compatible; right panel: incompatible). Strains cultured on PDA plates covered with cellophane membrane. Once hyphal tips of the two strains contact each other, the observation of fusion cells were conducted under microscope.

Characteristics of the Vegetative Incompatibility Reaction

Microscopic and Macroscopic Analyses of Hyphal Fusion

In many organisms, cell fusion plays an essential role in many developmental processes, such as sexual cells fusion and multinucleate cell-based organ formation. In filamentous fungi, during an early stage of hyphal anastomosis, the cell wall synthesizing enzymes and digestive enzymes in secretory vesicles are delivered to the point of contact. After exchange cellular contents of the contacted cells, new septa usually form near to the fusion site. This hyphal anastomosis increases nutrition and water utilization in the fungal colony. While cell fusion from different genetic background often results in the formation of heterokaryon, heterokaryon grows well if fused cells formed from genetically compatible individuals, whereas the fused cells formed from incompatible individuals show vacuolation and PCD, termed VI. The process of VI in some fungal species can be easily observed by the naked eye, when the incompatible pairs of strains grow on agar medium. There usually appears a black-pigmented band at the interface of two contacting fungal isolates (Fig. 1(A), yellow arrow), while there is no clear barrage between the fused vegetatively compatible isolates (Fig. 1(A), red arrow). This vegetative compatibility testing of pair-cultured isolates on agar has been used to analyze VCGs and natural populations in many fungi, including in *S. sclerotiorum*, *P. anserina* and *O. novo-ulmi*. The black-pigmented banding between two contacting fungal isolates is formed by degeneration of the fused cells and neighboring cells. These cells marked as vacuolation with increasing the size of vacuoles and then cytoplasmic granulation. Some contacted cells from different VCGs become shrinks (Fig. 1(B), yellow arrow). Scanning electron microscope (SEM) observation of hyphal fusion between incompatible strains showed that the fusion cells caused cytoplasmic shrinkage (Fig. 1(C), yellow arrow), while the fusion cells from compatible strains grew well (Fig. 1(C), red arrow). Transmission electron microscopy (TEM) observation of the fused cells from compatible pair strains revealed that cell wall fusion with normal vacuoles and new septa formed at the sites of anastomosis. In the incompatible fused cells, the plasma membranes of heterokaryon were disconnected, cytoplasm and vacuoles contents disappeared. Incompatible fuse leads to PCD without hyphal anastomosis. Therefore, the morphological changes of vacuoles and cytoplasm in the fusion cells act as an indicator of VI.

Identification of VCGs

VCGs identification is important to evaluate the genotypic and phenotypic diversity of fungal populations. Multiple techniques have been developed to identify VCGs in filamentous fungi.

Barrage assay

The barrage assay is a convenient method because it does not require additional specific genetic markers, and can be performed directly by pair-culturing of isolates. Potato dextrose agar (PDA) supplemented with McCormick's red food coloring has been applied for VCGs identification in *S. sclerotiorum* (Fig. 1(A)). PDA medium supplemented with bromocresol green pH indicator dye has been used for VCGs tests in *C. parasitica*. The medium supplemented with additional dyes could make the barrage more apparent to the naked eye.

Microscopy

Microscopic analysis of fused cells and neighboring cells to identify VCGs has been applied in some fungal species. Typical features including shrinkage of the plasma membrane and vacuolization of the cytoplasm serve as marker of VI. Mycelia plugs from different VCGs are placed on PDA plates covered with cellophane membrane. Pairs of plugs from the same VCG act as controls. When the hyphae from the two strains contact each other for 3–6 h, we can observe the microstructure of the fused cells under the microscope (Fig. 1(B)).

Visualization of labeled proteins during co-culture

When isolates from the same VCG contact each other, the two isolates can exchange cytoplasmic contents during anastomosis. The contacted cells from different VCGs will undergo PCD and prevent cytoplasmic communication. Therefore, if two tested isolates are labeled with two different fluorescent protein, we can observe the transmission of cytosolic fluorescent proteins during anastomosis; two fluorescent signals in the contacted cells indicate that two strains belong to the same VCG; only one fluorescent signal in the contacted cells at the region of contact indicates that the two strains belong to different VCGs and failed to fuse.

Auxotrophic complementation

Auxotrophic complementation can be used to test for VCGs. Hyphae from two isolates expressing different selective markers are allowed to intertwine at the interface region. If the pair of strains is compatible, the fused cells from the interface region can be able to grow by auxotrophic complementation.

Detecting the PCD of fused cells

In filamentous fungi, the VI reaction usually causes PCD of the fused cells and neighboring cells. We can test for the occurrence of cell death at the contacted area by staining dead cells, such as Evans blue staining. As a feature of early PCD, DNA fragmentation can be observed using TUNEL (terminal deoxynucleotidyl transferase) assays on VCGs identification. These methods for PCD detection are widely used among fungal pathogens.

The Genetics of Vegetative Incompatibility

The outcome of fused cells is dominated by self/nonself-recognition genes. If two contacted isolates have the same recognition genes, the hyphae from the interaction zone will successfully fuse and form a coherent colony. However, when the two isolates have difference at one or more of self-recognition loci, the fused hyphae in the interaction zone usually undergo PCD, manifested as VI. Therefore, the failure of hyphal fusion between VCGs often reflects genetic differences at the *het* or *vic* loci. In *N. crassa* and *P. anserina*, allelic and non-allelic VI systems have been established. In the allelic VI system, co-expression of incompatible alleles at the same locus leads to VI reaction, for instance *het-s*/HET-S in *P. anserina*. In non-allelic VI systems, interactions among unlinked incompatible alleles from different genes results in VI, such as *het-r* and *het-v*-mediated VI in *P. anserina*. Furthermore, the HET proteins that contain a common ~150 amino acid conserved HET domain usually contribute to VI reaction, and HET proteins widely exist in fungal genomes. In *P. anserina*, the proteins with HET domain acted as the mediator of PCD during the VI process. In *N. crassa*, 73 putative HET proteins have been identified via comparative population genomic analysis, but the roles of those HET genes in the process of VI remain to be investigated. Using the same approach, 44 proteins with HET domain were predicted in the genome of *S. sclerotiorum*. To date, the VI systems of three fungal species (*N. crassa*, *P. anserina*, and *C. parasitica*) as model fungi have well been studied.

In *N. crassa*, the locus (*mat-A1* and *mat-a1*) controls mating and sexual development, strains with null mutations in *mat A-1* are both heterokaryon compatible and sterile with *a* mating type strains. However, during vegetative growth, hyphae fusion of opposite mating type leads to growth inhibition and PCD, which is mediated by the tolerant (*tol*) locus. The *tol* gene contains HET domain and leucine-rich repeat regions (LRRs). The mutant *tol* acts as a specific suppressor of heterokaryon incompatibility. Furthermore, interactions between *het* genes (such as *un-24* /*het-6* and *het-c*/*pin-c*) were further confirmed to control VI.

In *P. anserina*, eight VI systems have been characterized; the function of allelic locus *het-s* and the nonallelic *het* loci (*het-c*, *het-e*, and *het-r*) depend on genes encoding HET domain proteins, which have been confirmed to function in triggering PCD. Typical *het* genes contain a HET domain at the N-terminal, a NACHT domain in the central, and a WD40 repeats domain at C-terminal. The NACHT domain contains LRRs and a pyrin domain (PYD). In plants and animals, as recognition of pathogen-associated molecular patterns, NACHT-containing proteins stimulate immune responses and regulate apoptosis. Proteins containing WD40 domain are involved in many life processes, including apoptosis, transcriptional regulation and immune responses. The NACHT-WD40 domain is functionally important in HET-E-triggered PCD reactions in fungi. Furthermore, the *het-s* allele encodes a prion form protein HET-s, it acts as an activation trigger of a cell death execution protein. In *C. parasitica*, six unlinked *vic* loci have been

identified and characterized. Among these VI systems, the function of *vic1*, *vic6*, and *vic7* depends on proteins containing HET domains, and *vic4* encoded protein has a NACHT-WD40 architecture.

The predicted proteins with HET domains are usually not conserved in fungi, thus it is difficult to define *het* genes via its orthologous relationships. Interestingly, heterologous expression of *het-c2* from *N. crassa* can also trigger a VI reaction in *Aspergillus niger*. This result indicated that the *het-c* homolog could function as a *het* gene in a different fungus, although this remains to be explored in different species. The function of un-24 triggering VI-mediated PCD shows the same function in *N. crassa* and its related species, but it does not function as a *het* gene in other species. Therefore, proteins containing a HET domain have diverse functions, and some of these proteins are involved in VI. Exploring the function of these proteins in VI processing will enhance our understanding of the polymorphism of *het* proteins.

The Signaling Pathways of Vegetative Incompatibility

The VI process involves many signaling pathways, including recognition of a non-self-signal, signal transmission, and triggering of PCD. Although the VI systems appear to be complex in different fungi, the cellular reactions to the VI signals might be similar. When two incompatible hyphae contact each other, shrinkage of the plasma membrane and vacuolization are frequently observed in fungi. Interestingly, vegetatively incompatible individuals from *Verticillium albo-atrum* and *Verticillium dahliae* can form heterokaryons via protoplast fusion, not via hyphal fusion. Interspecific and intraspecific heterokaryons formation could be improved by removing the cell wall. Therefore, the outcome of VI is controlled by nuclear and also associated with components affecting the cell wall or cell wall formation. Therefore, cell wall, plasma membranes and vacuoles could play important roles in VI reactions.

Heterotrimeric G proteins play an essential role in the signal-transduction pathways, including pheromone response and mating, pathogenesis, and non-self-recognition in eukaryotes. G proteins consist of three subunits including $G\alpha$, $G\beta$, and $G\gamma$. In *P. anserina*, one α subunit of G proteins (MOD-D) regulates the process of VI. Increasing the cAMP level suppresses the defects in vegetative growth caused by the mod-D1 mutation, while increased cAMP has no influence on the suppressor effect of the mod-D1 mutation during VI reaction, thus, the function of MOD-D in VI reactions is independent of the cAMP pathway. In *S. sclerotiorum*, three homologs of $G\alpha$, one of $G\beta$, and one of $G\gamma$ have been identified as G subunit proteins. With the exception of one $G\alpha$ subunit gene, the expression levels of the other four G protein subunit genes were significantly up-regulated during hyphal contact between incompatible individuals, while there is no expression change during anastomosis. Therefore, G proteins as multifunctional signaling proteins are also involved in transduction of VI signals in fungi.

In all eukaryotes, Calcium (Ca^{2+}), a ubiquitous second messenger, is involved in multiple biological processes. Ca^{2+} levels play an essential role during germling and hyphal fusion. Increasing intracellular Ca^{2+} levels can commonly trigger plasma membrane fusion of secretory vesicles. Furthermore, the process of activation of MAP kinases usually occurs at cell membrane. In *N. crassa*, membrane protein HAM-11 is involved in regulation downstream of the MAK-2 pathway, but the $\Delta ham-11$ mutant fails to undergo self-fusion. HAM-11 protein activates the MAPK signaling complex to achieve cell fusion. Another WD40 repeats-contained protein HAM-5 as a MAP kinase shows physically interaction with MEK-2 and MAK-2. HAM-5 oscillates with MAK-2 during hyphal fusion and controls the disassembly of the MAK-2 MAPK complex, but the $\Delta ham-5$ mutant fails to undergo self-fusion. Therefore, HAM-5 is important for the activation of MAK-2 cascade during VI reaction. MAK-2 pathway is also essential for transmitting the VI-mediated PCD signal to downstream during incompatible fungi fusion (Fig. 2).

In *N. crassa*, HET-C is a transmembrane protein, and the initial self/nonself recognition between two strains occurs in the cell membrane. Another protein HET-E is also related to endomembrane and cytoplasmic. In *P. anserina*, [HET-s] prion and HET-S (a soluble protein) that coexist in one cell will lead to the loss of membrane integrity and cell death. Thus, alteration of the stability of the cell membrane by HET proteins is an initial response after hypha fusion finally lead to VI-associated cell death reactions. In *Rosellinia necatrix*, cytological analysis shows that the VI-mediated PCD is a vacuole-mediated process. The integrity of vacuoles might act as an important role in the switch between compatible and incompatible reactions. In *P. anserina*, among *idi* genes (induced during incompatibility), *idi-1* is associated with the response to nutrient starvation and the VI process. IDI-1 is a cell wall protein localized at the septum, and rapamycin treatment could induce overexpression of *idi-1*. This treatment also shows hallmarks of VI, including increased septation, vacuolization and autophagy. Thus, IDI-1 could be involved in the TOR kinase pathway during VI reaction. *idi-7* is an ortholog of *Atg8* in *Saccharomyces cerevisiae*, which is involved in autophagy. Another *idi* gene, *pspA* (a subtilisin-like serine protease), has an ortholog in *S. cerevisiae*, and encode a vacuolar protease involved in autophagy. These observations suggested that VI reaction may be similar to autophagy, and this process is related to signal protein transportation from cell membrane to vacuole.

Most of the molecularly characterized proteins involved in VI have been identified as possessing a HET domain in fungi. In *S. sclerotiorum*, most HET genes are significantly upregulated during VI; while these candidate *het* genes are downregulated when VI reactions are suppressed. In *N. crassa*, a transcription factor encoded by the *vib-1* gene regulates *het* gene expression. Deletion or mutation of *vib-1* suppressed the VI reaction mediated by genetic differences *het* loci. Thus, proteins containing a HET domain are important for downstream functions during VI reactions. According to the transcriptional analysis in *P. anserina* and *N. crassa*, the top 100 up-regulated genes during the VI-mediated PCD reaction involve in cell signaling pathways or autophagy, which indicated that some common factors have the same function during VI reactions in both *P. anserina* and *N. crassa*. In *N. crassa*, many conserved eukaryotic factors are involved in regulation of germling fusion, such as MAP kinase modules, NADPH oxidases (NOX), and calcium-regulated factors. These signaling pathways are confirmed to play important roles in hyphal fusion in fungi (Fig. 2).

domains (NB-ACC, NACHT and AAA), and 3C-terminal domains (ANX, WD and TPR). Some fungal NLRs have enzymatic activities at N-terminal domains, such as Patatin with phospholipase and peptidase activities. These structures indicate that fungal NLRs have numerous functions in addition to their signaling function. As mentioned above, fungal proteins containing HET domains have function in VI-mediated PCD. In *P. anserina*, 10 of 16 characterized *vic* proteins contain a HET domain, and overexpression of a HET domain could initiate a VI-like PCD. The *vic2* and *vic4* loci in *C. parasitica* encode typical NLRs. In *S. sclerotiorum*, two proteins have an NB-ARC domain, two proteins contain a WD domain, and one protein has a NACHT domain among 44 predicted proteins containing a HET-domain. In *N. crassa*, patatin-like phospholipase-1 (PLP-1) with typical NLRs was identified, and the N-terminal phospholipase activity and central NBD are essential for triggering allorecognition and PCD in *P. anserina* and *N. crassa*. These observations indicated that the functions of fungal NLR-like proteins, including some HET proteins, are similar to the NLRs from animals and plants, and contribute to non-self recognition.

In plants and animals, NLR-mediated innate immunity is triggered by infection by various pathogens. Fungal NLRs-mediated VI also function in bacteria-fungi and virus-fungi interactions as a microbe-associated molecular patterns. Transcriptomic analyses of NLR-controlled VI revealed the activation of processes including cell wall modification, secondary metabolite production and autophagy; this is very similar to the responses induced by bacteria in plant or animal. The *vic2* system in *C. parasitica* has been confirmed to reduce virus horizontal transmission via triggering VI-mediated PCD. In *Arabidopsis*, the patatin domain could enhance the resistance to cucumber mosaic virus via triggering cell death, and the patatin domain in the *vic2* has similar function to initiate cell death in *C. parasitica*. Thus, VI in fungi leads to rapid cell death and increase antimicrobial activity, and NLR-controlled VI could reduce virus horizontal transmission during hyphal fusion of incompatible individuals.

Mycovirus Transmission

Mycovirus was first reported in cultivated mushrooms in 1962. With the application of high-throughput sequencing in mycovirus, more and more mycoviruses with different types were found in all four phyla of fungi. For the most mycoviruses, transmission is limited to intracellular transmission (cell to cell), while there has been reported some exceptions that break the restrictions of VI in fungi. SsHADV-1 has an extracellular phase and can infect its sister species of *Sclerotinia* directly via virus particles. Furthermore, some kind of vectors have been identified that facilitates mycovirus transmission. An insect, *Lycoriella ingénue*, can be a transmission vector to facilitates SsHADV-1 spread. A plant virus, cucumber mosaic virus (CMV), can naturally infect fungus *Rhizoctonia solani*, and *R. solani* isolates can also acquire CMV from plants during infection, which suggests that CMV can be transmitted in *R. solani* isolates via plants vector. Most mycoviruses have neither transmission vector nor extracellular phase, and these mycoviruses are limited to the intracellular life cycles, with lateral transmission among fungal populations via hyphal fusion and vertical transmission via producing sexual/asexual spores. In generally, mycoviruses can be spread through asexual spores with a high frequency rate. In *Basidiomycetes* fungi, mycoviruses can frequently enter into basidiospores. However, in ascomycetous fungi, most of mycoviruses could not enter into ascospores during sexual reproduction, exception for some mitoviruses and ourmia-like viruses, which may relate to mitochondrial inheritance. Mycovirus horizontal transmission between fungal isolates is mainly achieved through anastomosis. Therefore, hyphal anastomosis is essential for maintaining the mycovirus proportion in the natural fungal population.

Vegetatively compatible combination within and between individuals occurs with a high frequency, which promotes hyphal network formation and facilitates mycovirus transmission within a colony. However, most hyphal fusion between different VCGs of the same species triggers cell death. VI as NLR-mediated innate immunity in fungi can effectively block mycovirus transmission among fungal populations. The success of CHV1 application to biocontrol chestnut blight in Europe encouraged similar virocontrol of other fungal pathogens with mycoviruses. The same efforts to virocontrol chestnut blight in North America have failed due to the diversity in VCGs of *C. parasitica* isolates. In black *Aspergilli*, horizontal transmission of mycoviruses only occurs among the same VCGs under laboratory conditions. Therefore, horizontal transmission of mycovirus is usually considered to be limited to the strains belonging to the same VCG. Under the balancing selective forces, diverse organisms maintain polymorphisms of genes involved in innate immunity and VI systems. In *C. parasitica*, VI-related genes are under selective forces due to restriction the transmission of debilitation-associated viruses among fungal populations. This suggests that the polymorphisms of VCGs are the way to prevent transmission of viral disease.

The influence of VI systems on virus transmission has been well-studied in *C. parasitica*. Based on the *C. parasitica* strains isolated from a natural population with different *vic* genes, the ability of CHV1 transmission among different isolates shows negatively correlated with the number of different *vic* alleles between them. When donor and recipient strains have one different *vic* allele, the transmission frequency of CHV1 was 0.5, while transmission frequency decreased to 0.13 or lower when VCGs differed by two or more *vic* loci. In *C. parasitica*, there shows a significant negative correlation between PCD and the frequency of CHV1 transmission. In *S. sclerotiorum*, an RNA virus (SsDRV) cannot be transmitted to the strains that belong to different VCGs. Thus, VI is a main barrier for mycovirus horizontal transmission between different VCGs of *S. sclerotiorum*, and reduction of the frequency of VI-mediated PCD can promote virus horizontal transmission. In the CHV1-*C. parasitica* system, five of the six *vic* loci (except *vic4*) have confirmed to restrict mycovirus horizontal transmission among VCGs.

Mycoviruses can be Horizontally Transmitted Among VCGs

As VI is the main factor to restrict horizontal transmission of mycoviruses, the efficiency of mycoviruses transmission can be promoted by modifying VI systems. Based on the function of these five *vic* genes in CHV1 transmission, a super mycovirus donor

strain with disruption of four *vic* genes (*vic1a-2*, *vic3b-1*, *pix6-2*, and *vic7a-2*) has been engineered, a mixture of the two donor strains with *vic2-1* or *vic2-2* enables CHV1 to be transmitted easily under laboratory and natural conditions. Therefore, it could serve as an enhanced hypovirus vector via breaching the restriction of VI. Similarly modified VI systems in other fungi can be applied to facilitate mycoviruses horizontal transmission.

Current research revealed that some of mycoviruses can escape from the restriction of VI systems under the natural or laboratory conditions. In *S. sclerotiorum*, Sclerotinia sclerotiorum deltaflexivirus 2 (SsDFV2) and Sclerotinia sclerotiorum partiti-virus 1 (SsPV1) can be transmitted between different VCGs without the limitations of the VI system, and SsPV1 can even be transmitted to the other *Sclerotinia* species through hyphal contact. Two partitiviruses (HetRV3-ec1 and HetRV4-pa1) have been confirmed to easily transmit between different VCGs.

Potential Approaches to Enhance Mycovirus Transmission Between VCGs

VCGs shows high diversity in many filamentous fungi, but mycoviruses are still very common in different VCGs, suggesting that viruses can block VI system or have potential transmission bridge under natural conditions. In *R. necatrix*, Rosellinia necatrix fusarivirus 1 (RnFV1) (RNA element N10 carried in fungal strain NW10) can be horizontally transmitted between the two incompatible strains after co-inoculated on an apple tree for three years. It was unclear that any environmental factor changes help RnFV1 to break through the VI system in *R. necatrix* during the process of infecting the host plant. Therefore, unlike simple laboratory conditions, mycovirus transmission can break through the barriers of VI systems under certain natural conditions. It also has been reported that 1.5 mM Zinc chloride treatment was able to facilitate mycovirus transmission via increasing hyphal anastomosis and attenuating PCD in *R. necatrix* and some other fungi. In *N. crassa*, a cell death-activated zinc cluster transcription factor (CZT-1) acts as the regulator for cell death. Using UPLC-HRMS, some secondary metabolite productions have been found significantly shifted in *C. parasitica* during *vic3* incompatibility, such as a farnesyl-S-oxide analog resembling mating pheromones. Adding activated charcoal to the culture medium can also inhibit the VI reactions and promote the transmission of the mycovirus in *R. necatrix*. Some proteins located at cell wall (such as IDI1) may be affected by adding activated charcoal or $\text{Ca}^{2+}/\text{Zn}^{2+}$. Therefore, mycovirus transmission can be modified via eliminating the specific secretions of the strain or suppressing the VI reactions (Fig. 3).

With the development of high-throughput sequencing to gain viral genome information, more and more mycoviruses showed close phylogenetic relationships to plant viruses, suggesting that some mycoviruses could transmit in a cross-kingdom manner.

Fig. 3 The potential model of mycovirus horizontal transmission via breakthrough the barrage of VI systems. Strain A, strain B, and bridge strain belong to different VCGs, when strain A and strain B contact each other, the contacting cells will occur strong PCD reactions (red dotted arrow). To attenuate vegetative incompatibility, treatment with zinc compounds can enhance transmission efficiency of mycoviruses to strains with different genetic backgrounds. A bridge strain for mycovirus transmission also can improve mycovirus transmission between different VCGs, this bridge strain can be modulating fungal allelorecognition (disruption of *vic* genes) or the strain that infected by a certain virus (such as SsMYRV4) with suppressing host VI reactions. Mycovirus can be transmitted via different kinds of vectors, such as plants, mites, and insects, etc.

R. solani isolates can obtain and transmit CMV to the host plants, so CMV can be transmitted among different VCGs of *R. solani* in plant. Some mycoviruses are very similar to plant viruses in the order *Tymovirales*, these mycoviruses may replicate in both plant and fungi, and the mycoviruses should shuttle between plants and fungi when pathogenic fungi infect plant tissues, so these groups of mycoviruses may block the barrage of VI systems via vector plants. Conversely, a mycovirus may infect a host plant, bacteria, or protozoa transiently and then virus can be transmitted back to fungi (Fig. 3). In root rot fungi *Heterobasidion* spp., the transmission efficacy of mycovirus HetPV15-pa1 could increase from 0% to 50% among different VCGs if the donor strain was pre-infected with HetPV13-an1. Thus, co-infection with some viruses or bacteria could help other mycovirus transmission among VCGs by blocking VI-mediated PCD.

SsMYRV4 can suppress VI-mediated PCD to block the barriers of VI systems in *S. sclerotiorum*. VI-mediated PCD is controlled via transduction of VI signals, including recognition of strain-specific molecules via G-protein-coupled receptors (GPCRs) and NLRs, transduction of VI signals via MAK2 kinase and induction PCD via ROS signaling (Fig. 2). Thus, suppression of the expression of the key genes in these pathways would effectively block VI-mediated PCD and enable mycovirus horizontal transmission among VCGs (Fig. 3).

© 2021 Elsevier Ltd. All rights reserved.

Glossary

Casing The upper layer (55 mm) of the bilayer system for *A. bisporus* cultivation, formulated by mixing peat (75%–85%) and lime/chalk (15%–25%) followed by large amounts of water.

Fruitbody Multicellular fleshy structure bearing spores and used as a food and also known as mushroom, sporophore, sporocarp and toadstool.

Hyphal anastomosis The union of two hyphae allowing cytoplasmic exchange.

Mushroom compost The nutritional substrate for cultivated *A. bisporus* made by solid-state fermentation of cereal straw,

animal manure, gypsum and water over 14–20 days and then positioned as the lower layer (200 mm) of the bilayer cultivation system.

ORF Open reading frame.

ORFan ORF with no similarity to other described ORFs and no known function.

Phase 3 compost Mushroom compost colonised by *A. bisporus* mycelium for 17 days at 25°C.

Vegetative incompatibility A genetically controlled system which prevents two fungal strains from undergoing anastomosis.

VLP Virus-like particle.

Introduction

Two disease-causing viruses of the cultivated mushroom, *Agaricus bisporus*, have been characterized. For both diseases the viruses have been identified as part of multiple virus infections i.e., in the presence of other apparently asymptomatic viruses. Four million tonnes of *A. bisporus* mushroom fruitbodies are cultivated annually (value of ~US \$4.7bn) throughout the world and traded internationally enabling viral mixing and movement, and the accumulation of high viral loads. *A. bisporus* is cultivated in a bilayer system with a 55 mm non-nutritious casing layer above a 200 mm layer of composted cereal straw colonised by *A. bisporus* mycelium. This cultivation system is intensive enabling up to nine crops per year to be grown in the same room with cleaning and sterilization between each crop.

In the early 1950s a new disorder of the cultivated mushroom was described and named as La France Disease after the initial observations at the La France Farm in Pennsylvania, USA. The disease has since been reported in other U.S. farms and around the world. The symptoms involve slow mycelial and fruitbody growth, malformed mushroom fruitbodies and major crop loss (up to 100%) often observed as barren zones on the mushroom growing bed. La France disease is strongly associated with a 36 nm isometric virus-like particle (VLP) encapsidating nine double-stranded RNA (dsRNA) elements. Other VLPs have been isolated from diseased tissue, the bacilliform particle (19 nm × 50 nm) of the barnavirus, mushroom bacilliform virus (MBV) and 25 nm, 29 nm and 50 nm isometric particles, however their role in disease has not been established. The nine dsRNA elements of the 36 nm particle were collectively named La France isometric virus, or LIV and later by the more systematic name *Agaricus bisporus* virus 1 (AbV1).

In the late 1990s in the UK a new disease syndrome was described with disease symptoms superficially similar to La France disease, i.e., yield-loss (seen as bare patches with no mushrooms growing) and distorted fruitbodies, but without the characteristic presence of VLPs. Furthermore, this new disease had an additional symptom, a uniform brown discoloration on the mushroom caps. The name given to the new disease syndrome was Mushroom Virus X disease (MVX disease) and it is associated with multiple viral infections of up to 30 viral RNAs. Large scale sequencing of the RNAs associated with MVX-infected fruitbodies identified 18 unique viruses and 8 ORFans. Of these, only a single virus, *Agaricus bisporus* virus 16 (AbV16) and one uncategorized non-host RNA molecule (ORFan8) have been correlated with any symptom; cap browning. Brown Cap Mushroom Disease (BCMD) is now viewed as a viral disease distinct from MVX. Since 2000, the prevalence of the bare patches and distortions caused by MVX has declined while the brown cap symptoms have persisted and reported throughout Europe, North America and Asia. BCMD is economically important as brown discoloration is deleterious to quality (of white mushrooms) and therefore value, and the discoloration can occur after harvest causing friction between mushroom producers and buyers.

AbV1 and AbV16 are often found in co-infections with, MBV. Whether any form of synergistic or antagonistic relationship exists between these viruses, or any of the other many viruses infecting *Agaricus bisporus*, remains unknown. It is of note that the levels of MBV can increase by more than ten-fold when in a multiple infection with AbV1 compared to isolates with undetectable levels of AbV1. However, on its own MBV is not capable of producing any of the symptoms of either disease.

Fig. 1 Genome organization of AbV1. All segments are arranged 5' – 3' and the longest ORFs are shown as yellow annotations. Blue annotations indicate the presence of the shared motif (GGMAACGGCTAGTTKGCC). NCBI accession is shown above each segment. Dashed lines indicate the segment has not been sequenced with the sizes of these segments estimates based on gel electrophoreses.

La France Disease – *Agaricus Bisporus* Virus 1 (AbV1)

Genome Organization

The AbV1 genome comprises of six abundant, always present dsRNAs (L1, L2, L3, L4, L5 and M2) and three less abundant dsRNAs (M1, S1 and S2), with size range of 0.78–3.6 kbp (Fig. 1). If detectable, the less abundant dsRNAs are never found in isolation. Four of the abundant dsRNAs (L1, L3, L5 and M2) and M1 have been sequenced. L1 (3.4 kbp) has a single open reading frame (ORF) which codes for an RNA-dependent RNA polymerase (RdRp) domain containing protein of c. 122 kDa, however the 5' UTR of ~200 bp has not been fully sequenced and so the ORF may be slightly longer. L3 (2.8 kbp) contains a single ORF which codes for an 87 kDa protein and has a 29 nucleotide poly (A) tail on the coding strand. Both L1 and L3 have significant amino-acid similarity to RdRps and structural proteins respectively of members of the *Chrysoviridae*. L5, M1 and M2 code for proteins of size 82 kDa, 42 kDa and 38 kDa respectively, none of which have homology to any known proteins. The polyprotein encoded by L5 is known to be cytoplasmically located and not associated with the AbV1 virions. L3, L5 and M2 share an 18-base motif (GGMAACGGCTAGTTKGCC) in their 5' UTR. The less abundant segment M1 lacks this motif, and it is unknown if the L1 5' UTR contains it due to the incomplete sequencing.

Virion Structure and Composition

AbV1 virions are isometric particles with diameter estimates between 34–36 nm. Three polypeptides are associated with the virions, two abundant molecules of molecular mass 90 kDa and 120 kDa, and a less abundant molecule with estimated mass of either 115 kDa or 129 kDa. The less abundant polypeptide is the RdRp coded by L1. The two abundant polypeptides are presumably structural constituents of the capsid. The 90 kDa protein is coded by the L3 dsRNA, while the 120 kDa molecule is probably coded by L2 as this is the only unsequenced dsRNA of sufficient length to produce a protein of this size. It is not known, or whether it is physically possible, if single virions encapsidated all 9 dsRNA elements, or like other members of the *Chrysoviridae* family the genomic segments are encapsidated separately.

Taxonomy and Classification

Phylogenetic analysis of the RdRp coding region of the L1 segment indicates that *Agaricus bisporus* virus 1 is closely related to members of the family *Chrysoviridae* with dsRNA genomes, and is positioned within the genus *Betachrysovirus* of the *Chrysoviridae* (Fig. 2). It is of note that, unlike most of the classified fungal alphachrysoviruses which are asymptomatic in their hosts, members of the genus *Betachrysovirus* such as *Magnaporthe oryzae* chrysovirus 1 and *Alternaria alternate* chrysovirus 1, typically produce symptoms of retarded growth.

Fig. 2 Phylogenetic relationship of the *Chrysoviridae* and related species. Alignment of the predicated amino acid sequences of the given accessions was performed with MAFFT v7. Uninformative regions of the alignments were removed using Gblocks v0.91. Phylogenetic trees were constructed using Phylml 3 with SMS for best model selection. The numbers refer to the percentage branch support from 1000 bootstrap repetitions. Branches with less than 45% bootstrap support have been collapsed.

Biological Properties (Virus Host Relationships)

As well as La France, the disease has been variously known as X-disease, die-back, watery stipe and brown disease, reflecting the wide range of associated symptoms. The major characteristic symptom is localized bare patches on mushroom growing beds (die-back) caused by failure of the mycelium to colonize the casing and thus failure of mushrooms to emerge. Around the periphery of these die-back zones, the fruitbodies often fail to grow properly and show a characteristic “drumstick” phenotype, where stipes are elongated or swollen and the caps small and misshapen. Other symptoms include brown discoloration of internal tissue (as streaks), bent stipes and a tendency for premature maturation. The severity of the disease varies from a very few abnormal mushrooms to complete loss of the crop. The range of symptoms seems to be affected by the host genotype, the timing of the initial infection with more devastating symptoms occurring when infection occurs at an earlier stage during the mushroom production cycle, and cultural practices. The presence of the AbV1 dsRNAs in a mushroom fruitbody is not in itself sufficient to cause the disease phenotype, though symptomatic fruitbodies from an infected crop always contained the six major dsRNAs.

Epidemiology

AbV1 is spread between mushroom crops via anastomosis; predominantly when infected spores germinate on the mushroom bed, or directly via infected mycelium. It has been noted that infected mushrooms tend to mature early and release a huge number of spores. Like the overwhelming majority of fungal viruses there are no-known external routes to infection or natural vectors.

Diagnostics and Identification

The 36-nm particles of AbV1 can be detected by electron microscope. Gel separation of the dsRNAs has also been successfully used to detect the virus. The more sensitive techniques are PCR-based using the primers to the known RNA sequences of the virus.

Fig. 3 Genome organization of Abv16 and ORFan8. All segments are arranged 5' – 3' and the longest ORFs are shown as yellow annotations. Blue annotations show the presence and location of the shared motif (STTCAGSGTBBVWSHAGCRGTAAWT). An indication of segment variability is given as the number of single nucleotide polymorphisms per kilobase of sequence (snp/kb). NCBI accession is shown above each segment.

Fig. 4 Phylogenetic relationship of the members of the proposed family *Ambsetviridae* compared to selected members of alphavirus-like supergroup. Alignment of RdRp domains in the predicted amino acid sequences of members of the alphavirus-like supergroup was performed with MAFFT v7. Uninformative regions of the alignments were removed using Gblocks v0.91. Phylogenetic trees were constructed using Neighbor joining. The numbers refer to the percentage branch support from 100 bootstrap repetitions. Branches with less than 50% bootstrap support have been collapsed.

Fig. 5 Typical symptom expression of Brown Cap Mushroom Disease (a) single brown in an experimental bed, (b) single brown in commercial production, (c) group of browns amongst white mushrooms, (d) off-white and brown mushrooms.

Control

There is no natural immunity to AbV1 in any cultivated *A. bisporus* strains. There is a degree of vegetative incompatibility between strains; browns, creams and whites will not readily anastomose therefore rotating strains at the mushroom farm can lead to some protection. However, successful control of La France disease has been achieved by substantial increases in hygiene at mushroom farms; steam treatment of the growing room and equipment and the use of air filtration to exclude infected mushroom spores.

Brown Cap Mushroom Disease – *Agaricus Bisporus* Virus 16 (AbV16)

Genome and Virion Structure

AbV16 is a non-particulate, multipartite virus with four segments ranging in size from 558 to 1949 bases (Fig. 3). The ORFs of AbV16 RNA1 and AbV16 RNA2 encode an RdRp and viral methyltransferase respectively. The function of AbV16 RNAs 3 and 4 are unknown. Each of the AbV16 RNA's contains a 25 base motif in the 3' UTR. ORFan8 does not contain the 3' motif but it is included as part of the causative agent for BCMD, as its levels correlate with the degree of cap browning and with the levels of the components of AbV16. ORFan8 and the AbV16 segments are polyadenylated, and considered to represent the genome of a positive sense, single-stranded RNA virus by close relation to other single-stranded RNA viruses. No virion structure has been identified for this virus.

Classification

AbV16 has been classified as within the alphavirus supergroup by phylogenetic analysis of the Pfam RdRp_2 domain of AbV16 RNA1. It is proposed to be a member of a new viral family, the *Ambsetviridae*, which includes homologs of RNAs previously not classified as viruses but identified from Transcriptome Shotgun Assembly and Expressed Sequence Tag databases (Fig. 4). A recently described virus identified in *Rosellinia necatrix* is a probable member of this family. The organisms identified from the searches suggest the *Ambsetviridae* is a family of fungal and plant viruses. Two of these organisms have homologs to three components of AbV16 and a further seven have homologs to two components. No homologs have been found to the viral segment AbV16 RNA4 or ORFan8.

Viral Expression and Disease Development

AbV16 and ORFan8 are present in infected mushrooms at two distinct levels. Low level infection results in slightly discolored mushroom caps only detectable by precision colorimeters. However, in visibly brown mushrooms, the RNA levels are 10^3 – 10^4 times

higher, intermediate levels have not been detected. The factors determining this persistent to acute transition, from low to high abundance, are not fully understood. There appears to be a stochastic element as brown mushrooms can be observed apparently randomly distributed throughout a bed of white mushrooms (Fig. 5). It is known that the transition occurs early in fruitbody development and so may be associated with host cell division. It is possible the transition may also embrace the “quasi-species” concept, involving the generation of a wide range of sequence variants overcoming host defences, as AbV16 RNAs1 and 2 show high sequence variability.

Epidemiology

Commercial inoculum for mushroom culture involves high standards of hygiene, testing and documentation of axenic cultures of *A. bisporus*. Infection is likely to occur at mushroom growing farms or “phase 3 compost” producers from infected sources (cultivated or wild *A. bisporus*), and associated with inadequate hygiene procedures.

The intra-mycelial movement of AbV16 within compost culture has been shown to be slow at 40 mm/day (compared with 120 mm/day and >200 mm/day for two other *A. bisporus* viruses, AbV12 and AbV7 respectively). Therefore, a point-infection of AbV16 on mushroom growing beds will have limited range for enlargement during the short growing period. Wide-spread outbreaks of BCMD are likely to have resulted from an infection during phase 3 compost production and/or compost mixing, transport and distribution. A further interesting feature of AbV16 is that its levels in mycelium in compost or laboratory culture can decline dramatically over time to become undetectable. The reasons for this decline are unknown, however AbV16 has been found only as part of a multiple viral infection and it is possible that inter-viral competition associated with specific viral combinations may play a role.

Diagnosis

High level infection of AbV16 and ORFan8 can be detected visually as brown discolored mushroom fruitbodies and low-level infection can be detected by sensitive colorimeter ($\Delta E > 15$ or $L/b < 12$).

AbV16 and ORFan8 can be detected qualitatively by agarose gel separation or PCR. The increased sensitivity of quantitative PCR enables detection of early, low level infection in mycelium in compost/casing and fruitbodies.

Glossary

ER-associated degradation (ERAD) A cellular quality control mechanism ensuring efficient removal of misfolded and/or unassembled proteins from the endoplasmic reticulum (ER) lumen and their subsequent elimination by the cytoplasmic ubiquitin–proteasome system.

H/KDEL receptors Seven-transmembrane proteins primarily required for the retention of soluble ER resident proteins in the endoplasmatic reticulum in yeast and mammalian cells.

Heterokaryon Coexistence of two or more genetically different nuclei in a common cytoplasm. Importins: A family of proteins that transport macromolecules into the eukaryotic nucleus.

Killer virus system A killer virus system consists of a helper totivirus and a satellite double-stranded (ds) RNA encoding the unprocessed precursor of a secreted protein toxin that also gives functional immunity.

Preprotoxin Toxin precursor in the cytoplasm of a killer yeast which is post-translationally imported into the secretory pathway for toxin processing, maturation, and secretion.

Satellite dsRNA An encapsidated dsRNA that is dependent on a helper virus for encapsidation and replication.

Spheroplasts A yeast cell whose cell wall has been enzymatically removed.

Introduction

Although double-stranded (ds) RNA viruses had previously been identified in filamentous fungi, dsRNA viruses in yeast were identified as determinants of the killer phenomenon in *Saccharomyces cerevisiae* and are now known to be associated with the presence of cytoplasmically inherited members (totiviruses) of the genus *Totivirus* in the family *Totiviridae*, which are frequently found in various yeast genera. Among these, the killers of *S. cerevisiae*, *Zygosaccharomyces bailii*, *Hanseniaspora uvarum*, *Torulaspora delbrueckii* and *Ustilago maydis* – the latter being the cause of corn smut – are best characterized. Interestingly, the absence of RNA interference (RNAi) seems to be a prerequisite for dsRNA viruses existence as killer systems were so far merely found in RNAi-deficient yeast species whereas RNAi-proficient yeasts did not develop any killer systems during evolution. Characteristic for all killers is the secretion of a certain type of protein toxin that is lethal to sensitive strains of different species and genera without a direct cell-to-cell contact. Cell killing is usually achieved in a receptor-mediated process, requiring initial toxin binding to components of the outer yeast cell surface (such as β -1,6-D-glucans, α -1,3-mannoproteins, or chitin) and subsequent toxin transfer to a secondary plasma membrane receptor. Depending on the toxin, final lethality can be caused by plasma membrane damage, G1- or S-phase cell-cycle arrest, apoptosis, and/or by rapid inhibition of DNA synthesis.

In the yeasts *S. cerevisiae*, *Z. bailii*, *H. uvarum*, *Torulaspora delbrueckii* as well as in the maize smut fungus *U. maydis*, the killer phenotype is cytoplasmically inherited and caused by an infection with dsRNA viruses. Since the majority of fungal mycoviruses are noninfectious and symptomless in the corresponding host, they are often classified as cryptic viruses or virus-like particles (VLPs). All known fungal viruses spread vertically by cell–cell mating and/or heterokaryon formation. In *S. cerevisiae*, diploids formed by mating of a killer with a sensitive strain are likewise killers, as are all haploid progeny of subsequent meiosis. In contrast, virus-free strains are usually sensitive nonkillers, while those containing *Saccharomyces cerevisiae* virus L-A (ScV-L-A) and a toxin-encoding M-dsRNA are killers (see below). Sensitive strains survive mating with killers, and cytoplasmic mixing of the multiple M-dsRNA copies during zygosis accounts for the inheritance pattern during meiosis. Extracellular spread of virions is generally hampered by the rigid yeast and fungal cell wall barrier, and fungal viruses have adopted a strategy of transmission via mating and hyphal fusion (which occurs frequently in nature) making an extracellular route of spread dispensable. While some of these viruses can be associated with adverse phenotypic effects on the fungus (like La France disease in *Agaricus bisporus*, plaque formation in *Penicillium*, and hypovirulence in *Cryphonectria*), dsRNA viruses and their associated satellite dsRNAs are responsible

Table 1 dsRNA encoded killer toxin systems of various yeast species

Totivirus/satellite dsRNA	Virus host	Function of virus	dsRNA (kb)	Encoded protein(s)
ScV-L-A	<i>Saccharomyces cerevisiae</i>	Helper virus	L _A (4.6)	Gag, major capsid protein; Gag-Pol, RDRP ^a
ScV-M1	<i>Saccharomyces cerevisiae</i>	Satellite dsRNA	M ₁ (1.6)	K1 preprotoxin
ScV-M2	<i>Saccharomyces cerevisiae</i>	Satellite dsRNA	M ₂ (1.5)	K2 preprotoxin
ScV-M28	<i>Saccharomyces cerevisiae</i>	Satellite dsRNA	M ₂₈ (1.8)	K28 preprotoxin
ScV-Mlus	<i>Saccharomyces cerevisiae</i>	Satellite dsRNA	M _{lus} (2.1–2.3)	Klus preprotoxin
UmV-H	<i>Ustilago maydis</i>	Helper virus	H (6.1)	Gag, major capsid protein; Gag-Pol, RDRP ^a
UmV-P1	<i>Ustilago maydis</i>	Satellite dsRNA	M _{P1} (1.4)	KP1 preprotoxin
UmV-P4	<i>Ustilago maydis</i>	Satellite dsRNA	M _{P4} (1.0)	KP4 toxin
UmV-P6	<i>Ustilago maydis</i>	Satellite dsRNA	M _{P6} (1.2)	KP6 preprotoxin
HuV-L	<i>Hanseniaspora uvarum</i>	Helper virus	L _A (4.6)	Gag, major capsid protein; Gag-Pol, RDRP ^a
HuV-M	<i>Hanseniaspora uvarum</i>	Satellite dsRNA	M _{Hu} (1.0)	KT470 toxin precursor
ZbV-L	<i>Zygosaccharomyces bailii</i>	Helper virus	L _{Zb} (4.6)	Gag, major capsid protein; Gag-Pol, RDRP ^a
ZbV-M	<i>Zygosaccharomyces bailii</i>	Satellite dsRNA	M _{Zb} (2.1)	prepro-zygocin
TdV-LAbarr	<i>Torulaspora delbrueckii</i>	Helper virus	L _A (4.6)	Gag, major capsid protein; Gag-Pol, RDRP ^a
TdV-Mbarr-1	<i>Torulaspora delbrueckii</i>	Satellite dsRNA	M _{barr-1} (1.7)	Kbarr-1 preprotoxin

for a killer phenotype which is based on the secretion of a polypeptide toxin (killer toxin) that is lethal to a variety of sensitive yeast and fungal strains. With the exception of toxin-secreting strains of *Z. bailii*, killer toxin production is usually associated with specific immunity, protecting the corresponding killer yeast against its own viral toxin.

DsRNA Viruses and Killer Phenotype Expression in *S. Cerevisiae*

On the basis of killing profiles and the lack of cross-immunity, four major killer types (K1, K2, K28, Klus) have so far been identified in *S. cerevisiae*. Each of them produces a specific killer toxin and a self-protecting immunity component. Killer phenotype expression correlates with the presence of two types of dsRNA species stably persisting in the cytoplasm of the infected host: the genomic dsRNA of the helper virus, ScV-L-A, and one of four toxin-coding satellite dsRNAs (ScV-M1, ScV-M2, ScV-M28 or ScV-Mlus). The ScV-L-A and M-dsRNAs are separately encapsidated into capsids encoded by ScV-L-A dsRNA and are present in high copy number in the yeast cell cytoplasm. *In vivo*, ScV-L-A does not confer a phenotype nor does it lead to host cell lysis or slower cell growth. While the killer phenotype can be transmitted to sensitive yeast cell spheroplasts (harboring ScV-L-A) by transfection with purified ScV-M (either during mating or cotransformation with a dsDNA plasmid), extracellular transmission occurs rarely, if at all, in nature. The survival strategy adopted by these dsRNA viruses appears to be a balanced host interaction resulting in stable maintenance, little if any growth disadvantage, and vertical transmission. Mechanisms of exiting and entering the host cell through its tough and rigid cell wall are rendered unnecessary by relatively efficient horizontal transmission during the frequent zygosis events in yeast. Acquisition of a toxin-encoding M satellite dsRNA provides positive selection for both this dsRNA and ScV-L-A, since virus-free segregants are killed.

As summarized in **Table 1**, the linear dsRNA genome of ScV-L-A contains two open reading frames (ORFs) on its plus-strand RNA: ORF1 encodes the major capsid protein Gag necessary for encapsidation and viral particle structure, the second gene (ORF2) represents the RNA-dependent RNA polymerase Pol which is *in vivo* expressed as a Gag–Pol fusion protein by a –1 ribosomal frameshift event. In contrast to ScV-L-A, each M-dsRNA genome contains a single ORF coding for a preprotoxin (pptox) representing the unprocessed precursor of the mature and secreted toxin that also gives functional immunity. Since each toxin-coding ScV-M dsRNA depends on the coexistence of ScV-L-A for stable maintenance and replication, the killer viruses resemble classical satellites of ScV-L-A. Although the presence of all four M-dsRNAs with different killer specificities in a single cell is excluded at the replicative level of the M genomes, this limitation can be by-passed by introducing cDNA copies of other pptox genes into a natural killer strain. Thereby, the artificial construction of a stable triple-killer strain producing three different virus toxins (K1, K2 and K28) and showing multiple toxin immunity at the same time is feasible.

As typical for many dsRNA viruses, the replication cycles of ScV-L-A and M-dsRNAs depend on the presence of specific packaging signals at or near the 3'-end of the viral single-stranded RNA (ssRNA) transcript. These RNA regions function as viral binding sites (VBSs) and consist of a stem–loop structure whose stem is interrupted by an unpaired protruding A residue (**Fig. 1**). For replication of ScV-L-A, two sequence elements are essential: an internal replication enhancer (IRE), which is essentially indistinguishable from the VBS, and a small stem–loop structure 5 bp from the 3'-terminus (3'-TRE). While ScV-L-A contains just a single VBS element, the toxin-coding transcripts of M1, M28, and MZb (encoding the *Z. bailii* viral toxin zygocin) each have two such VBS domains. Interestingly, no VBS elements are present in the dsRNA sequence of Mlus and Mbarr-1, indicating that alternative cis- active elements can be predicted to exist in the 3'-RNA region which act as signal for replication, replication-enhancement and packaging. *In vivo*, these VBS elements are

Fig. 1 Comparison of the 5'- and 3'-ssRNA sequences in ScV-L-A and in the toxin-coding transcripts of its satellites ScV-M1, ScV-M28, ScV-Mlus, TdV-Mbarr-1, and ZbV-M. Potential *cis*-active sequences within the 3'-termini as well as poly-A rich regions are indicated (VBS, viral binding site; IRE, internal replication enhancer; TRE, 3'-terminal recognition element). Length of the (+)ssRNA are shown in base pairs (bp).

cis-active sequences that are recognized by Gag–Pol and subsequently packaged into new viral particles. The replicase reaction on the (+)ssRNA template takes place *in vitro* (i.e., within the viral capsid) and requires a correct 3'-end sequence and structure. Within the intact and mature virion, conservative transcription of the plus-strand from the dsRNA template requires recognition of its very 5'-terminal sequence by Gag–Pol. In M28 (as in other dsRNAs), the plus-strand initiates with 5'-GAAAA(A); since there are little additional conserved sequences immediately downstream, this terminal recognition element (5'-TRE) may be all that is necessary for transcription initiation (Fig. 1).

Viral Replication Cycle

Yeast ScV-L-A virions are noninfectious icosahedral particles 39 nm in diameter that show certain similarities to core particles of mammalian orthoreoviruses and rotaviruses. Each ScV-L-A particle consists of a single copy of the 4.6 kb L-A dsRNA genome which is encapsidated by 60 asymmetric dimers of the 76 kDa coat protein Gag and two copies of the 171 kDa Gag–Pol fusion protein. During conservative replication, the single-stranded plus-strand RNA (L-A(+)ssRNA) is transcribed within the viral particle (*in vitro*) and subsequently extruded into the cytoplasm where it serves as (1) messenger RNA for translation into the viral proteins Gag and Gag–Pol and (2) RNA template which is packaged into new viral particles. Once this coat assembly is completed, Gag–Pol functions as replicase, synthesizes a minus-strand, and generates the dsRNA genome of the mature virus. The replication cycle of the toxin-coding M satellite dsRNA resembles that of L-A with the exception that each M virion can accept two copies of the smaller M-dsRNA genome before the ssRNA transcript is extruded into the cytoplasm; in analogy to certain DNA bacteriophages, this phenomenon has been named 'headful packaging'.

Viral Preprotoxin Processing and Toxin Maturation

In totivirus infected killer yeasts, the toxin-encoding M(+)ssRNA transcript is translated on free cytosolic ribosomes into a pptox precursor which is post-translationally imported into the secretory pathway for further processing, maturation, and toxin secretion. Interestingly, intracellular pptox processing in killer strains of either *S. cerevisiae* (K1, K2, K28), *Z. bailii* (zygotin), or *U. maydis*

Fig. 2 Analogy of toxin precursor processing in totivirus infected killers of *S. cerevisiae*, *Z. bailii*, *T. delbrueckii* and *U. maydis*. Schematic outline of the known and predicted precursor proteins (preprotoxins) encoding either a heterodimeric α/β toxin (K1, K28, Klus and Kbarr-1) or a monomeric virus toxin (K2, zygocin, KP4). Signal peptidase (SP) cleavage, Kex2p endopeptidase as well as Kex1p carboxypeptidase processing sites are indicated. Potential N-glycosylation sites are indicated with black circles (aa, amino acids).

(KP4) has been demonstrated as being mechanistically conserved, resulting in the secretion of a biologically active monomeric or α/β heterodimeric virus toxin. Based on hydrophobicity plots and *in silico* sequence analysis, a preprotoxin structure is also predicted for the Klus and Kbarr-1 killer toxins, however further experimental data is required to determine the exact nature and function of the postulated subunits (Fig. 2).

For K28 killer strains containing ScV-M28, pptox processing has been intensively studied and is well understood. Mature K28 toxin represents a heterodimer whose α - and β -subunit is covalently linked by a single disulfide bond. Since the unprocessed toxin precursor resembles a secretory protein, it contains a hydrophobic signal sequence for pptox import into the ER lumen followed by the toxin subunits α (10.5 kDa) and β (11.0 kDa) which are separated from each other by a potentially N-glycosylated γ -sequence (Fig. 2). During passage through the yeast secretory pathway the K28 toxin precursor is enzymatically processed to the biologically active heterodimer in a way that is highly homologous to prohormone (e.g., preproinsulin) conversion in mammalian cells. In a late Golgi compartment, the N-glycosylated γ -sequence is removed by the action of the furin-like endopeptidase Kex2p, the C-terminus of β is trimmed by carboxypeptidase Kex1p cleavage, and the biologically active protein is secreted as a 21 kDa α/β heterodimer whose β -C-terminus carries a four-amino-acid epitope (HDEL) that represents a classical ER retention signal. Since

Fig. 3 Preprotoxin processing and toxin secretion in an ScV-M28 infected killer yeast. After *in vivo* translation of the preprotoxin coding killer virus transcript, the toxin precursor is post-translationally imported into the endoplasmic reticulum (ER) through the Sec61 complex. Signal peptidase (SP) cleavage in the ER lumen removes the N-terminal signal sequence (pre-region) and protoxin folding is mediated by luminal ER chaperones. The intervening γ -sequence is N-glycosylated and a single disulfide bond between α and β is generated. In a late Golgi compartment, Kex2p endopeptidase cleaves the pro-region, removes the γ -sequence, and carboxypeptidase Kex1p cleavage trims the C-termini of both subunits, leading to the secretion of mature α/β toxin whose β -C-terminal HDEL motif is uncovered and thus accessible for interaction with the HDEL receptor of the target cell. SV, secretory vesicle; CW, cell wall; PM, plasma membrane. Adapted from Schmitt, M.J., Breinig, F., 2002. The viral killer system in yeast: From molecular biology to application. *FEMS Microbiology Reviews* 26, 257–276, with permission from Blackwell Publishing.

this signal is initially masked by a terminal arginine residue (HDELR), ER retention of the toxin precursor is prevented until the protoxin enters a late Golgi compartment where Kex1p cleavage uncovers the HDEL signal of the toxin (Fig. 3).

Endocytosis and Intracellular Transport of the K28 Virus Toxin

In contrast to most virally encoded yeast killer toxins, which do not enter their host but rather kill a sensitive cell by disrupting plasma membrane function, K28 is taken up by receptor-mediated endocytosis and subsequently targeted to the secretory pathway. After initial binding to α -1,3- and/or α -1,2-mannotriose side-chains of a 185 kDa cell wall mannoprotein, K28 interacts with its secondary toxin receptor, the HDEL receptor Erd2p, at the plasma membrane level (Fig. 4). Responsible and essential for this interaction is a short-amino-acid motif at the carboxyterminus of the K28 β -subunit (HDEL) which normally functions as ER targeting/retention signal for ER-resident chaperones such as Kar2p/BiP and Pdi1p. Once the K28/Erd2p complex is endocytosed, K28 is retrogradely transported from endosomes *via* Golgi to the ER, from where the toxin retrotranslocates into the cytosol to finally reach its target(s) in the nucleus. Due to the high affinity binding between the toxin's HDEL-motif and the cellular HDEL receptor within the low pH-environment of the endosomal and Golgi compartment, the receptor/toxin complexes are likely associated until they reach the neutral pH inside the ER. However, further research is needed to fully understand the exact mechanism(s) of how the toxin/receptor complexes are *in vivo* recognized by the endocytotic machinery and how the internalization and retrograde transport through the different cellular compartments is regulated. In fact, endocytotic uptake and retrograde transport is a common strategy realized in certain prototypes of bacterial toxins such as *Pseudomonas* exotoxin A, *Escherichia coli* heat-labile toxin (HLT), or even Shiga toxin. All these protein toxins are family members of microbial A/B toxins which are usually internalized by receptor-mediated endocytosis, followed by reverse secretion *via* Golgi and ER. Interestingly, many of these toxins contain putative ER retention signals at their C-termini, and H/KDEL-dependent mechanisms have, therefore, been postulated to be of major importance for toxin entry into mammalian cells. In this respect, a major difference between the yeast K28 virus toxin and bacterial A/B toxins is that K28 itself is produced and secreted by a eukaryotic (yeast) cell, and therefore the C-terminal ER-targeting signal in the toxin precursor is initially masked by a terminal arginine residue which ensures successful ptox passage through the early secretory pathway. Once the toxin has reached a late Golgi compartment, Kex1p cleavage removes the β -C-terminal arginine residue and thereby uncovers the ER targeting signal of the virus toxin. To ensure proper access of the ER targeting signal to the H/KDEL receptor of the sensitive target cell, many A/B toxins (including the yeast K28 virus toxin) contain a unique disulfide bond at or near the C-terminus. Consequently,

Fig. 4 Schematic model of the endocytotic uptake and retrograde transport of K28 into the ER. In a first step, the β -subunit of the mature K28 α/β heterodimer binds in an energy-independent process to α -1,3- and/or α -1,2-mannotriose side-chains of the primary mannoprotein receptor (R1) in the yeast cell wall (CW). In a second step, K28 crosses the cell wall and subsequently interacts with the yeast HDEL receptor Erd2p (R2) at the plasma membrane level. The C-terminal HDEL motif of the toxin's β -subunit is crucial for the toxin/receptor interaction. Finally, each receptor/toxin complex is internalized by clathrin-mediated endocytosis and retrogradely transported from endosomes through the Golgi apparatus into the ER, where K28 is released from the HDEL receptor and subsequently retrotranslocated into the yeast cytosol. Thereby, K28 binding to and/or release from the HDEL receptor Erd2p critically depends on the pH environment of the respective subcellular compartment; receptor/toxin complexes are stably associated in a more acidic pH environment (pH < 6.8) which is typical for endosomes and Golgi, whereas the complexes dissociate at the neutral pH of the ER lumen (pH > 6.8).

mutant toxin variants with altered inter- and/or intra-subunit disulfide bonding are nontoxic *in vivo* due to the incapability to reach their intracellular target. Thus, disulfide bond formation in microbial and viral A/B toxins is of major importance to ensure interaction competence of the toxins with the H/KDEL-receptor of the particular target cell.

ER Exit and Nuclear Entry of the K28 Virus Toxin

During host cell penetration, K28 retrotranslocates from the ER into the cytosol and dissociates into its subunit components. The β -subunit is subsequently polyubiquitinated and proteasomally degraded while the cytotoxic α -subunit enters the nucleus and causes cell death (Fig. 5). ER exit of the α/β heterodimeric toxin is presumably mediated by the Sec61 complex, termed translocon, which functions as major transport channel in the ER membrane of yeast and higher eukaryotes. In yeast, each translocon resembles a core heterotrimeric complex consisting of the transmembrane protein Sec61p and the two smaller subunits Shh1p and Sss1p. Besides being the major channel for co- and post-translational protein import into the ER, Sec61p is also involved in the export and removal of misfolded and/or mis-assembled proteins from the secretory pathway to initiate their proteasomal degradation in the cytosol. In addition to its central function in protein quality control in the ER, Sec61 is also responsible for ER retrotranslocation of certain plant, microbial and viral A/B toxins such as ricin, cholera toxin, *Pseudomonas* exotoxin A, and the yeast K28 virus toxin. In contrast to microbial and plant A/B toxins, however, retrotranslocation of K28 from the ER lumen is independent of ubiquitination and proteasome activity and classical components normally involved in ER-associated protein degradation (ERAD) are not required for ER exit of this virus toxin. In K28 intoxicated cells, toxin translocation competence in the ER strongly depends on the activity of luminal Hsp70 chaperones (such as Kar2p/ BiP and Pdi1p), Hsp40 cochaperones (such as Scj1p and Jem1p), and additionally requires proper maintenance of calcium homeostasis in the ER (Fig. 5). So far it is not known what cellular component within or near the ER membrane is responsible for toxin exit, but K28 might be a fruitful tool to identify a novel transport pathway for protein transport across the ER membrane.

K28 Affects DNA Synthesis, Cell-Cycle Progression, and Induces Apoptosis

Although the cytotoxic α -component of K28 (10.5 kDa) can enter the nucleus by passive diffusion, extension of α by a classical nuclear localization sequence (NLS) significantly enhances its *in vivo* toxicity due to faster and more efficient nuclear import mediated

Fig. 5 Retrotranslocation of the K28 virus toxin from the ER and its lethal effect in the nucleus. After endocytotic uptake and retrograde transport via Golgi and ER, the toxin is gated through the Sec61p export channel by the help of luminal ER chaperones such as Pdi1p, Kar2p, Jem1p, and Scj1p. Thereby, Pdi1p plays a major role in the toxin retrotranslocation step. The “disulfide rearrangement model” schematically illustrates how reactivity of the sulfhydryl residues in the β -subunit changes during K28 intoxication. Under acidic pH conditions (pH 4.7), K28 is structurally stable as a disulfide-bonded α/β heterodimer. At neutral pH of the ER lumen, a free sulfhydryl (SH) residue in the β -subunit deprotonates which leads to the formation of an active thiol (S⁻). The nucleophilic attack of the reactive thiol and the heterodimer dissociation is prevented by the activity of Pdi1p, enabling exit of K28 as α/β heterodimer from the ER. In the pH-neutral and Pdi1p-free environment of the cytosol, the nucleophilic attack induces a disulfide bond rearrangement and subsequent release of the monomeric α -subunit from the heterodimer. Thereafter, β is poly-ubiquitinated via Ubc4p (E2) and Rsp5p (E3) and proteasomally degraded while α enters the nucleus and causes cell death. Within the nucleus, the α -toxin interacts with essential host proteins involved in eukaryotic cell-cycle control and causes cell death through G1/S cell-cycle arrest and inhibition of DNA synthesis. Cellular components of the ER quality control system ERAD (such as Cue1p, Ubc7p, Der3p/Hrd1p, Ubc6p, and Der1p) are not involved in ER-to-cytosol export of the K28 virus toxin (ERAD components are shown in gray color). Reproduced and adapted from Leis, S., Spindler, J., Reiter, J., Breinig, F., Schmitt, M.J., 2005. *Saccharomyces cerevisiae* K28 toxin – A secreted virus toxin of the A/B family of protein toxins. In: Schmitt, M.J., Schaffrath, R. (Eds.), *Topics in Current Genetics 11: Microbial Protein Toxins*. Berlin, Heidelberg: Springer, pp. 111–132, with kind permission of Springer Science and business Media.

by α/β importins of the host. Within the nucleus, α interacts with host proteins of essential function in eukaryotic cell cycle control and initiation of DNA synthesis. Thus, as the virus toxin targets evolutionary highly conserved proteins with basic and central function, toxin resistance mechanisms based on mutations in essential chromosomal host genes hardly occur *in vivo*, indicating that the toxin has developed a very efficient strategy to penetrate and kill its target cell. Most interestingly, while high toxin concentrations (10 pmol or higher) cause necrotic cell killing via cell-cycle arrest and inhibition of DNA synthesis, treatment with low doses of viral killer toxins (<1 pmol) results in an apoptotic host-cell response triggered by the accumulation of reactive oxygen species, ROS (Fig. 6). Since toxin concentration is usually low in the natural environment of a killer yeast, toxin-induced apoptosis is probably an important prerequisite for efficient cell killing. Furthermore, since apoptosis is also important in the pathogenesis of virus infections in mammals, it is not surprising that toxin-encoding yeast killer viruses (as has been shown for ScV-M1 and ScV-M2) can also induce

Fig. 6 Receptor-mediated toxicity of the viral killer toxins K1, zygocin, and K28. Killing of a sensitive yeast is envisaged in a two-step process involving initial toxin binding to receptors within the cell wall (R1) and the cytoplasmic membrane (R2). After interaction with the plasma membrane, ionophoric toxins such as K1 and zygocin disrupt cytoplasmic membrane function, while K28 enters the cell by endocytosis and diffuses into the nucleus to cause cell death (note that the cell surface receptors R1 and R2 are different in all three toxins; see also table inset). At high toxin doses (>10 pmol) sensitive cells arrest in the cell cycle with pre-replicated DNA (1n; left panel), while cells treated with K28 in low concentrations (<1 pmol) respond with apoptosis as shown by typical apoptotic markers such as chromosomal DNA fragmentation (TUNEL-positive cells), accumulation of reactive oxygen species (ROS) and phosphatidylserine exposure at the external surface of the plasma membrane detected by annexin-V staining (right panel).

a programmed suicide pathway in noninfected yeast. Although viral killer toxins were shown to be primarily responsible for this phenomenon, yeast killer viruses are not solely responsible for triggering a cell death pathway in yeast.

Lethality of Membrane Damaging Viral Killer Toxins

Yeast viral killer toxins kill sensitive cells in a receptor-mediated fashion by interacting with receptors at the level of the cell wall and the cytoplasmic membrane (Fig. 5). The initial step involves rapid toxin binding to a primary receptor R1 which is localized within the mannoprotein or β -1,6-glucan fraction of the cell wall. In the second step the toxin translocates to the plasma membrane and interacts with a secondary receptor R2 (Fig. 6). To date, only the membrane receptors for K1 and K28 have been identified. Kre1p, an O-glycosylated cell surface protein initially GPI-anchored to the plasma membrane and involved in β -1,6-glucan biosynthesis and K1 cell wall receptor assembly, was identified as plasma membrane receptor of killer toxin K1. In case of K28, the HDEL receptor Erd2p has been demonstrated to be responsible for both efficient K28 binding to and endocytotic uptake from the yeast plasma membrane. Once bound to the plasma membrane, ionophoric virus toxins (such as K1 and zygocin) disrupt cytoplasmic membrane function by forming cation-selective ion channels, while K28 enters the cell and acts in the nucleus: DNA synthesis is rapidly inhibited and cells arrest at the G1/S boundary of the cell cycle (Fig. 6).

Ion channel formation in yeast membranes induced by the K1 virus toxin was initially reported using patch-clamping techniques as a result from direct toxin action. However, this observation is inconsistent with the complete resistance seen in immune yeast cell spheroplasts, and so far receptor-independent channels have been observed, neither in yeast membranes nor in *Xenopus laevis* oocytes. Similar to K1 and K2, zygocin represents a membrane-damaging virus toxin which is produced and secreted

by ZbV-M infected killer strains of the osmotolerant spoilage yeast *Z. bailii*. Zygocin itself is a monomeric nonglycosylated protein toxin with an unusual broad killing spectrum, being equally active against phytopathogenic as well as human pathogenic yeasts including *Candida albicans*, *C. glabrata*, *C. tropicalis*, and *Sporothrix schenckii*. Since even filamentous fungi such as *Fusarium oxysporum* and *Colletotrichum graminicola* are effectively killed by the toxin, zygocin represents a virus toxin with significant antimycotic potential. Similar to K1 and K2 but significantly more efficient, zygocin disrupts plasma membrane integrity and causes rapid cell killing. Its ionophoric mode of action has been reinforced by *in silico* sequence analysis, identifying a stretch of potential α -helical conformation that forms an amphipathic structure characteristic for membrane-disturbing antimicrobial peptides such as alamethicin, melittin, and dermaseptin. In addition, this feature is accompanied by a transmembrane helix at the C-terminus of zygocin which is predicted to favor a membrane permeabilizing potential, not by activating native ion channels but rather by establishing pores by itself after toxin oligomerization. It is therefore assumed that the hydrophobic part in zygocins' amphipathic α -helix is responsible for toxin binding to the target cell. The postulated model of zygocin action resembles that of human α -defensins. In analogy to alamethicin, toxicity of zygocin is probably mediated by incorporation of its transmembrane helix into the plasma membrane, a process solely driven by the natural transmembrane potential of the energized yeast and fungal plasma membrane. Thus, zygocins' mode of action portrays the lethal mechanism of antimicrobial peptides that are produced by virtually all higher eukaryotes. Mechanisms of resistance against antimicrobial peptides are rare and often limited to changes in the composition of the cytoplasmic membrane. In major contrast to mammalian cells, the outer leaflet of yeast and fungal membranes is enriched in negatively charged lipids. Due to the cationic net charge of antimicrobial peptides (including zygocin), an affinity to these lipids facilitates toxin adsorption to the target membrane. Consistent with that, deletion of chromosomal genes whose gene products affect plasma membrane lipid composition (such as *PDR16* and *PDR17*) causes a dramatic decrease in zygocin sensitivity because toxin binding to the plasma membrane is largely prevented in the genetic background of a yeast *pd16/17* mutant. In contrast to K1, a zygocin-specific membrane receptor is not required for its *in vivo* toxicity as the physicochemical properties of zygocin allow efficient plasma membrane interaction independent of any membrane receptor or docking protein. Although the more recently discovered killer toxins Klus and Kbarr-1 likewise show an interesting broad killing spectrum similar to that of zygocin (i.e., killing yeasts such as *S. cerevisiae*, *Hanseniaspora* sp., *Cluyveromyces lactis*, *Schizosaccharomyces pombe*, *Candida albicans*, *C. tropicalis*, *C. dubliniensis*, *C. kefir*, *C. glabrata*, *C. parasitopsis*, *C. krusei*, *Yarrowia lipolytica*, and *Hansenula mrakii*), their precise mode and side of action is completely unknown and needs further investigation.

Self-Protection in Killer Virus-Infected Yeast – Toxin Immunity

For many decades it was unknown how a killer virus-infected yeast protects itself against its own secreted toxin. In killer yeast, functional immunity is essential for survival since the toxins often target and inhibit central eukaryotic cell functions. This is in major contrast to bacterial toxins such as cholera toxin and Shiga toxins which selectively kill eukaryotes, thus making immunity dispensable in a prokaryotic host. So far, only the mechanism of protecting immunity against the K28 virus toxin has been elucidated. It has been shown that K28 killer cells take up external toxin (either produced by itself or by other K28 killers) and translocate it back to the cytosol where the reinternalized α/β toxin rapidly forms a complex with the pptox precursor that has not yet been imported into the ER. Within this complex, the K28 heterodimer is selectively ubiquitinated and proteasomally degraded while the pptox moiety of the complex is in part released to be either imported into the ER (to give active virus toxin) or to complex a newly internalized K28 heterodimer. In this process, the amount of cytosolic ubiquitin is critical for immunity and overexpression of mutant ubiquitin (blocked in polyubiquitin chain formation) results in a significant decrease in toxin secretion and a suicidal phenotype based on nonfunctional immunity. Alternatively, decreasing cytosolic ubiquitin causes an increase in toxin secretion, while immunity is not impaired as sufficient pptox is available for K28 complex formation. This simple and highly efficient mechanism ensures that a toxin-producing killer yeast is fully protected against the lethal action of its own toxin. In contrast to K28 immunity, the precise mechanism(s) of self-protection against the ionophoric virus toxins K1, K2 and zygocin is still obscure and remains largely unknown.

Glossary

Mycoviruses Viruses that infect and propagate fungi.

Polyadeniration Addition of a poly (A) tail to 3' UTR of mRNA or viral plus-stranded RNA. In eukaryotes, polyadenylation is part of the process that produces mature mRNA for translation.

Rapid amplified of cDNA ends (RACE) This technique can provide the sequence of an RNA transcript to the 5' end (5' RACE-PCR) or 3' end (3' RACE-PCR) of the RNA.

RNA-dependent RNA polymerase (RdRP) Enzyme that catalyzes the replication of RNA from an RNA template.

Viruses with multipatite genomes The essential genome is divided among several genomic segments (segmented genome) that are either separately encapsidated in identical capsids.

Introduction

Fungi are infected by viruses, named as mycovirus. Recently, numerous mycoviruses are reported to cause epigenetic phenomena. Historically, mycoviruses were found in diseased *Agaricus bisporus* mushroom or *Aspergillus foetidus*, human pathogenic fungi over 50 years ago. Mycoviruses are primarily classified into four groups based on their genomic structure: single-stranded DNA (ssDNA), positive single-stranded RNA (+ ssRNA), negative single-stranded RNA (– ssRNA), and double-stranded RNA (dsRNA). In general, mycoviruses with dsRNA genomes are classified into six families based on the amino acid sequence of the RNA-dependent RNA polymerase (RdRp), the genomic structure, the virion structure. These families are: the *Totiviridae* (nonsegmented genome), the *Partitiviridae* (2 segments), the *Megabirnaviridae* (2 segments), the *Chrysoviridae* (3–5 segments), the *Quadriviridae* (4 segments), and the *Reoviridae* (9–12 segments) (Ghabrial *et al.*, 2015). Reovirus genome consists of 10–12 segments of dsRNA; each of the dsRNA segments has m7GpppNm cap structure at the 5'-end, and lack a 3' poly (A) tail. Partitiviruses genomes generally consist of 2 segments of dsRNA; each of the dsRNA segments has interrupted poly (A) tail at the 3'-end of the coding strands.

Alternavirus has 3–4 dsRNA segments; each of the dsRNA segments has intact stretched poly (A) tail at the 3'-end of the coding strands, which trait is a unique molecular property as segmented double-stranded RNA viruses. Although the number of reports on mycovirus articles has been increasing in recent years, there are only five reports describing alternaviruses. Here, we introduce intriguing characteristic properties of alternavirus, primarily focusing on *Alternaria alternata* virus 1 (AaV1) and *Aspergillus foetidus* dsRNA mycovirus (AfV-F), which are similar in size to dsRNA viruses in the families *Totiviridae*, *Partitiviridae*, and *Chrysoviridae*, and while the genomic structures of the dsRNA viruses in three families are completely different. Based on our findings for AaV1, AfV-F, and other three alternaviruses, we propose a new family, “*Alternaviridae*”, to accommodate them.

Genome Organization

The virions of AaV1 and AfV-F contain four unrelated linear, separately encapsidated, monocistronic dsRNA segments (1.4–3.6 kbp in size; Table 1). The largest segment, dsRNA1 encodes for the RdRp. DsRNA2, and dsRNA3 might encode for the major capsid protein (CP). The dsRNA segment 4 encodes for proteins of unknown function. The genomic structure of AaV1, type species of the genus *Alternaviridae*, and that of AfV-F are schematically represented in Fig. 1. It is noteworthy that all of the coding strands of the four dsRNA genomes have 3'-poly (A) tails ranging from 36 to 50 nt in length and stretches of poly (U) at the 5' terminus of the non-coding strand in all of the four dsRNAs was detected by 5'-RACE.

In the AaV1, both the 5'- and 3'-terminal sequences of all four dsRNAs are significantly conserved. Even in AfV-F, the 5'- and 3'-terminal sequences are highly conserved between the four RNA segments. The nucleotide sequences preserved in each are different between AaV1 and AfV-F (Fig. 2). These terminal sequences may be involved in the replication cycles of these dsRNAs depending on each RdRp of AaV1 and AfV-F. There is no evidence that these four dsRNAs are transcripts from host genomic DNA, which proved by southern hybridization experiments carried out with cDNA probes derived from the four dsRNAs of AaV1 in the EGS 35–193, *Alternaria alternata*.

Virion Properties

The buoyant densities of virions of AaV1 is in the range of 1.35–1.40 g/cm³ in CsCl. After treatment with chloroform–butanol followed by PEG precipitation, virus particles were purified by CsCl density equilibrium centrifugation. AaV1 virions are isometric, about 33 nm in diameter, and are similar in size to those of dsRNA viruses in the families *Totiviridae*, *Partitiviridae*, or *Chrysoviridae*.

Fig. 1 Genome organization of two alternaviruses. *Alternaria alternata* virus 1 (AaV1), and *Aspergillus foetidus* dsRNA mycovirus (AfV-F). The genome consists of four dsRNA segments; each monocistronic. The RdRp ORFs (nt 49–3498 on AaV1 dsRNA1, nt 53–3426 on AfV-F dsRNA1), the P2 ORFs (nt 53–2587 on AaV1 dsRNA2, nt 49–2454 on AfV-F dsRNA2), the P3 ORFs (nt 52–2331 on AaV1 dsRNA3, nt 51–2231 on AfV-F), the P4 ORFs (nt 51–1232 on AaV1 dsRNA4, nt 51–1793 on AfV-F).

Generally, each virion contains only one of the four genomic dsRNA segments. The four dsRNA segments are packaged separately in individual virus particles, with different buoyant densities; the dsRNA 1 segment is mainly detected in the fraction of buoyant density 1.40 g/cm³, while dsRNA 2 and dsRNA 3 segments are detected in the fractions of buoyant density 1.38–1.39 g/cm³, the dsRNA 4 segment is detectable in the fraction of buoyant density 1.35 g/cm³, although it is barely detectable. Therefore, the dsRNA-containing fractions varied depending on the size of the packaged dsRNA segments in the particles. After purification by CsCl density equilibrium centrifugation, the dsRNA-containing fractions were used for observation of virus particles by electron microscopy. Isometric virus particles with a diameter of about 33 nm were routinely observed (Fig. 3(a)). Approximately 97 kDa protein was detected as the major band, which might be coat proteins encoded by dsRNA 2 and dsRNA 3 (Fig. 3(b)).

Biological Effects of Alternavirus on Their Host

The AaV1 infected strain EGS 35–193 (ATCC), *Alternaria alternata* showed an abnormal phenotype, including reduced mycelial growth, aerial mycelial collapse, and unregulated pigmentation. In order to investigate whether the high concentration of AaV1 dsRNAs are responsible for this impaired growth, we attempted to eliminate or reduce the dsRNAs from the host fungus strain EGS 35–193. By exposing the strain to cycloheximide during hyphal tip isolation, we obtained an isolate E118, in which the amounts of the dsRNAs were reduced. In the isolate E118, the amount of dsRNA was reduced to about one tenth as compared to the parent strain, EGS 35–193. The isolate E118 restored normal mycelial growth and pigmentation, suggesting that the high titer of AaV1 caused attenuated mycelial growth of host fungus, strain EGS 35–193, *Alternaria alternata*. After inoculation on PDA agar medium for 24 h, regular-shaped mycelia were observed in the low titer of the isolate E118, but irregular and poor mycelia were observed in the original high titer strain

AaV1

AfV-F

Fig. 2 Comparison of the 5' and 3' UTRs of the four dsRNA segments of AaV1 and AfV-F. Multiple alignments were obtained using CLUSTAL XII (and some manual adjustments) with the nucleotide sequences of the 5' UTR (a) and the 3' UTR (b). Asterisks signify identical bases at the indicated position (shaded) and colons specify that three out of four bases are identical at the indicated positions.

Fig. 3 (a) Negative contrast electron micrograph of particles of *Alternaria alternata* virus 1. (b) Purified AaV1 proteins stained with Coomassie Brilliant Blue.

EGS35-193. In addition, abnormally enlarged vesicles appeared in mycelial cells of EGS 35-193. Bursting of these enlarged vesicles was observed around the hyphal cells. Only a few small vesicles were observed in cells of the low titer isolate E118. These results indicate that the reduced copy number of the dsRNAs in the restored isolates might be responsible for restoring normal morphology.

Proteins Encoded by Alternaviruses

The large dsRNA segment (dsRNA1) of alternaviruses so far sequenced contains a single large ORF coding for RdRp. A multiple alignment of the amino acid sequences of the putative RdRp encoded by the AaV1 dsRNA1 with RdRps of AfV-F, AsV341, FpAV1, and FgAV1 is shown in Fig. 4. Eight conserved motifs characteristic of RdRps of dsRNA viruses of simple eukaryotes were found in

Fig. 4 Multiple alignment of RdRp amino acid sequences from AaV1, AfV-F, AsV341, FpAV1, and FgAV1. The alignment was performed using Clustal X ver. 2.0 and trimmed to include the 8 conserved core regions of RdRp (indicated by solid lines), using Seaview ver. 4.0. Asterisks signify identical residues (shaded) at the indicated positions; colons signify highly conserved amino acid residues within a column; numbers in parentheses correspond to the number of amino acid residues separating the motifs.

the ORFs of the dsRNA1 in the five alternaviruses. The two putative RdRps encoded by AfV-F and AsV341 are very closely related to each other (identity: 99.6%). The two putative RdRps encoded by FpAV1 and FgAV1 are also very closely related to each other (identity: 98%). The RdRp encoded by AaV1 exhibits lower sequence similarities with that of AfV-F (identity: 36%), or that of FpAV1 (identity: 34%), while the identity between the RdRps of AfV-F and FpAV1 is 47%.

Although the putative RdRps encoded by the five alternaviruses appear to be closely related to each other, they are distantly related to members of any dsRNA virus family, including the *Totiviridae*, *Chrysovriidae*, and *Partitiviridae*, where even in the most conserved GDD motif, the glycine (G) residue is replaced by an alanine (A) in cases of the five alternaviruses (Fig. 4).

Phylogenetic analyses of their putative RdRp gene reveal that the five alternaviruses revealed distinct clade apart from the three families, *Totiviridae*, *Chrysovriidae*, and *Partitiviridae* (Fig. 5). Indeed, the genome structures of the dsRNA viruses in the three families are completely different. Alternaviruses have four dsRNA segments of 1.5–3.6 kbp, which are similar in size to dsRNA viruses in the family *Chrysovriidae* that possess four dsRNA segments of 2.4–3.6 kbp. In contrast, viruses in the *Totiviridae* and *Partitiviridae* families have single or two dsRNA segments, respectively. Thus, the alternaviruses appear to be evolutionarily related to but not members of the family *Chrysovriidae*.

3' Poly (A) Structure of Alternaviruses

It is noteworthy the coding strands of genomic dsRNAs in the alternaviruses contain 3' poly (A) tails, which are supposed to range from 33 to 50 nt in length. There was a possibility that a single-stranded (ss) form of dsRNAs was present in larger amounts than double-stranded (ds) form. In order to investigate whether the ratio of the AaV1 ssRNA to dsRNA form, northern blot analyses using three probes types were performed to determine the relative abundance of viral ssRNA and dsRNA; hybridization experiments were performed with probes for positive-strand RNA, negative-strand RNA, or both strands (dsDNA probes). If the positive-strand RNA were present in much greater quantities than the dsRNA, the signals detected by the positive-strand-specific probe should have been stronger than those detected by the negative-strand-specific probe or by a DNA probe that can detect both strands. However, there was no significant difference in the intensities of signals detected by the three probes, indicating that little single-stranded form of dsRNAs exists in the alternavirus, and most of the dsRNAs are present as genomic RNA rather than the replicative form of the ssRNA genome (Table 2).

Evolutionary Relationships Among Chrysoviruses

In recent years, the discovery of many mycoviruses has been reported. Historically, totiviruses and partitiviruses have been found widely not only fungi such as ascomycetes, yeast and mushrooms belonging to basidiomycetes such as *Agaricus* but also other simple eukaryotic organisms such as protozoa or oomycetes. Chrysoviruses discovered from *Penicillium chrysogenum* with four double-stranded RNAs were classified by Gabriel as members of the family *Chrysovriidae* independent from *Partitiviridae*, in EoV

Fig. 5 A phylogenetic analysis of the RdRp sequences of Alternaviruses and selected mycoviruses in the *Totiviridae*, *Chrysoviridae*, *Partitiviridae* families. An unrooted phylogenetic tree based on the neighbor-joining method was performed using the program MEGA 10. The numbers at nodes represent bootstrap values as percentages estimated by 100 replicates. The following viruses in the family *Totiviridae* were included in the phylogenetic analysis (abbreviations in parenthesis): *Helminthosporium victoriae* virus 190S (HmV190S); *Sphaeropsis sapinea* RNA virus 1 (SsRV1); *Sphaeropsis sapinea* RNA virus 2 (SsRV2); *Giardia lamblia* virus L1 (GaRV-L1); *Leishmania* RNA virus 1-1 (LRV1-1); *Leishmania* RNA virus 2-1 (LRV2-1); *Saccharomyces cerevisiae* virus L-A (ScV-L-A); *Saccharomyces cerevisiae* virus L-BC (ScV-L-BC). The following viruses in the family *Chrysoviridae* were included in the phylogenetic analysis (abbreviations in parenthesis): *Agaricus bisporus* virus 1 (AbV1); *Amasya cherry disease associated chrysovirus* (ACD-CV); *Helminthosporium victoriae* virus 145S (HmV145S); *Penicillium chrysogenum* virus (PcV); *Fusarium oxysporum* chrysovirus 1 (FoCV1). The following viruses in the family *Alternaviridae* were included in the phylogenetic analysis (abbreviations in parenthesis): *Alternaria alternata* virus 1 (AaV1); *Aspergillus foetidus* dsRNA mycovirus (AaV-F); *Aspergillus mycovirus* 341 (AsV341); *Fusarium poae* alternavirus 1 (FpAV1); *Fusarium graminearum* alternavirus 1 (FgAV1). The following viruses in the family *Partitiviridae* were included in the phylogenetic analysis (abbreviations in parenthesis): *Atkinsonella hypoxylon* partitivirus (AhPV); *Rhizoctonia solani* virus 717 (RsV717); *Helicobasidium mompa* partitivirus V1-1 (HmPV-V1-1); *Fusarium poae* virus 1 (Fupo-1).

Table 2 Comparison between AaV-1 and dsRNA viruses in three mycovirus families

Virus family (virus name)	Number of dsRNA genome	Segments size (kbp)	Virus particle	3' poly (A)	5' Cap
Alternavirus	4	1.5–3.6	isometric 33 nm	33–50 nt	
Totivirus	1	4.6–6.7	isometric 40 nm	not found	not found
Partitivirus	2	1.4–2.2	isometric 33 nm	20–30 nt	not found
Chrysovirus	4	2.4–3.6	isometric 35 nm	not found	not found
Megabirnavirus	2	6.5–7.0	isometric 50 nm	not found	not found
Reovirus	10 ~ 12	1.1–3.5	isometric 60 nm	not found	found

3rd edition, 2008. The viruses of these families and the proposed family Alternaviridae can be mixed infectiously in one host cell. To date, mycoviruses infecting these hosts have been discovered from more than hundreds of simple eukaryotes in more than 20 families. However, there are only five reports of the alternaviruses as hosts of three saprophytes, namely the genera *Alternaria* spp., *Fusarium* spp., and *Aspergillus* spp.

As one of the characteristics of the alternaviruses, it is to have intact poly (A) structures at the 3' ends of their dsRNA genomes, which is the first discovery as segmented double-stranded RNA viruses. In AaV1, the poly (A) structure at the 3' end has been proved to exist also in the double-stranded RNA genome extracted from within the purified virus particles. Recent studies by the authors have also provided data supporting the presence of a cap structure on the 5' ends of the dsRNA genomes.

Glossary

Casing A layer of peat moss placed on top of the growing beds to encourage sporophore formation.

Introduction

Mushroom bacilliform barnavirus is the type species and still only member of the *Barnaviridae*. In the U.S.A in 1948, a disease of the cultivated mushroom *Agaricus bisporus* was discovered on a property in Pennsylvania that had a major impact on the mushroom industry and fungal pathology in general. It was characterized by poorly colonised mycelium and misshapen fruiting bodies (sporophores) with long thin stipes and small globular caps producing a drumstick-like appearance, or they were thickened with a barrel-like appearance. The poor colonization of the compost and casing by infected mycelium often produced characteristic bare patches on the growing beds and reduced yields. The disease was named La France disease and a virus was implicated as a possible cause in 1960, after it was shown that the disease could be transmitted to healthy cultures by hyphal anastomosis. In 1962, 3 different virus-like particles were identified, two of which were spherical (25 nm and 29 nm), and the third was a 19 nm × 50 nm elongated or bacilliform particle with rounded ends. Subsequently a 34–36 nm spherical particle with a dsRNA genome (La France infectious virus, LFIV) has been identified as the causal agent of La France disease.

The bacilliform virus particle was of particular interest as almost all mycoviruses identified to that point had a spherical or isometric morphology. 19 nm × 48 nm bacilliform virus-like particles were subsequently identified in the ascomycete *Microsphaera mougeotti*, and 17 nm × 35 nm bacilliform particles were also observed in the deuteromycete *Verticillium fungicola*, itself a pathogen of *A. bisporus*. However no relationship with mushroom bacilliform virus (MBV) and these bacilliform particles has been established.

Originally named mushroom virus 3 (MV3), the virus was subsequently renamed mushroom bacilliform virus (MBV). The viral genome was identified as single-stranded (ss), positive-sense RNA, and the virus was classified by the International Committee on Taxonomy of Viruses (ICTV) as the exemplar virus of the species *Mushroom bacilliform barnavirus* (genus *Barnavirus*, Family *Barnaviridae*). The family name derives its roots from *Bacilliform RNA virus*. MBV remains the only barnavirus identified to date.

MBV remains the only barnavirus characterized to date, however next generation sequencing and metagenomics studies have recently identified another virus with similarity to MBV. Analysis of RNA sequences isolated from the plant pathogenic fungus *Rhizoctonia solani* identified a near-complete viral sequence that grouped closely with MBV on a phylogenetic tree, had a similar genome arrangement, albeit lacking an ORF1 suggesting the sequence was incomplete, and shared amino acid sequence identity, particularly in ORF3, the viral encoded RdRp (47% identity). Termed *Rhizoctonia solani* barnavirus 1 (RsBarV1; KP900904), the incomplete sequence is yet to be ratified as a barnavirus by the ICTV. Subsequent examination of public Transcriptome Shotgun Assembly (TSA) GenBank databases using BLAST search algorithms has since identified another near-complete virus sequence with a high degree of similarity to both BsBarV1 and MBV, named *Colobanthus quitensis* associated barnavirus 1 (CqABV1), detected in the Antarctic pearlwort *Colobanthus quitensis*. If ratified, this would be the first barnavirus identified from a plant species, however it is also possible that the sequence was derived from an associated unidentified fungus, rather than *C. quitensis* itself. Virus characterization studies, including identification of a bacilliform virus particle, are required to determine if these newly identified sequences are true barnavirus genomes.

MBV Virion Properties

The MBV virion M_r is 7.1×10^6 , with a buoyant density in Cs_2SO_4 of 1.32 g/cm³. Virions are stable between pH 6 and 8 and ionic strength of 0.01–0.1 M phosphate.

MBV Virion Structure and Composition

MBV has a bacilliform or bullet shaped morphology, with particles generally 19 nm × 50 nm in size (Fig. 1). Virions contain a single major CP of 21.9 kDa and there are approximately 240 molecules in each capsid. Virions encapsidate a single linear molecule of a positive-sense ssRNA, 4.0 kb in size. The complete 4009-nt sequence is available (Acc No U07551). The RNA has a viral 5' linked protein or viral genome-linked protein (VPg) and lacks a poly(A) tail. RNA constitutes about 20% of virion weight.

Fig. 1 Electron micrograph of mushroom bacilliform virus particles. The bar represents 100 nm.

Fig. 2 The mushroom bacilliform virus (MBV) genome arrangement.

MBV Genome Organization and Expression

The RNA genome (4009 nt) contains four major and three minor ORFs and has 5'- and 3'-UTRs of 60 nt and 250 nt, respectively (Fig. 2). ORFs 1–4 encode polypeptides of 20, 73, 47, and 22 kDa, respectively. The deduced amino acid sequence of ORF2 contains 3 conserved chymotrypsin-related serine protease sequence motifs. Blast searches of the deduced ORF2 amino acid sequence show similarity to serine proteases encoded by plant sobemoviruses. ORF2 also encodes the VPg. ORF3 contains the $GX_3TX_3NX_nGDD$ amino acid sequence shared by the putative RNA-dependent RNA polymerases (RdRps) of positive-sense ssRNA viruses and has similarity to the RdRps of sobemoviruses, enamoviruses and poleroviruses. ORF4 encodes the capsid protein (CP). ORFs 5–7 encode 8, 6.5, and 6 kDa polypeptides, respectively. The polypeptides potentially encoded by ORFs 1, 5, 6, and 7 show no significant similarity to known polypeptides. The negative strand of MBV contains seven small ORFs of unknown significance. These potentially encode polypeptides ranging from M_r 65K to M_r 105K.

The MBV genome arrangement and transcription/translation strategies are strikingly similar to those of a number of plant viruses, particularly poleroviruses and sobemoviruses. MBV probably also uses similar strategies to express its gene products, including leaky ribosomal scanning for expression of ORF2, ribosomal frameshifting for expression of the RdRP, and subgenomic RNA for expression of the CP. Of these, only subgenomic RNA has been confirmed *in vivo*. In a cell-free system, genomic length RNA directs the synthesis of major 21-kDa and 77-kDa polypeptides and several minor polypeptides of 18–60 kDa. The full-length genomic RNA and a sgrNA (0.9 kb) encoding ORF4 (CP) are found in infected cells. Virions accumulate singly or as aggregates in the cytoplasm. However the MBV life-cycle has yet to be determined.

MBV Evolutionary Relationships

As discussed earlier, the deduced MBV RNA-dependent RNA polymerase (RdRP) sequence shows most similarity to the RdRP of the putative barnavirus RsBarV1, grouping closely together on a phylogenetic tree (Fig. 3). In addition, the deduced MBV RdRP amino acid sequences share striking similarity with those of some plant viruses, particularly sobemoviruses, poleroviruses, and enamoviruses (Fig. 3). This, together with the similarity of the MBV and sobemovirus/polerovirus genome arrangements, suggests that MBV may have shared a common ancestor with these plant virus groups in the distant past.

MBV Transmission and Host Range

MBV is transmitted horizontally through infected mycelium and it is yet to be determined if the virus can be transmitted in spores. There is no known insect vector. Although morphologically similar viruses to MBV have been identified in the field agaric, *A. campestris*, it is unknown whether these particles are related to MBV. Consequently MBV remains the only barnavirus identified to date.

Fig. 3 Neighbor-joining tree of the mushroom bacilliform virus (MBV) RdRp compared to RdRPs of a number of plant viruses and the putative barnavirus RsBarV1, generated using MEGA X v10.0.4. Sequences were aligned using the Clustal W implemented in Genious V11.1.5 (<http://www.geneious.com>), using the cost matrix: BLOSUM default setting (1000 bootstrap replicates), and the tree was constructed with Treeview. Although rooted by outgroup (BYDV-PAV, barley yellow dwarf virus) this is an unrooted tree. CYDV-RPV = cereal yellow dwarf virus-RPV; SBMV = southern bean mosaic virus; RYMV = rice yellow mottle virus; PEMV = pea enation mosaic virus; BWYV = beet western yellows virus; PLRV = potato leafroll virus; RsBarV1 = *Rhizoctonia solani* barnavirus 1. The accession numbers of the sequences used in the analysis were PLRV (D00530), CYDV-RPV (NC004751), BWYV (NC004756), PEMV (NC003629), RYMV (NC001575), SBMV (DQ875594), MBV (U07557), BYDV-PAV (EF043235), RsBarV1 (KP900904).

Botybirnaviruses (*Botybirnavirus*)

Mingde Wu, Guoqing Li, Daohong Jiang, and Jiatao Xie, Huazhong Agricultural University, Wuhan, China

© 2021 Elsevier Ltd. All rights reserved.

Nomenclature

Boty Originates from the Latin name of the host fungus "*Botrytis*"

birna Refers to the bipartite dsRNA genome

Glossary

Anastomosis The fusion between two hyphae leading to their cytoplasmic exchange.

Conidia Asexual, non-motile spores of fungi, a major asexual reproduction structure for most ascomycetes.

Hypovirulence A phenomenon of reduced virulence for fungal pathogens, and sometimes is caused by viral infection.

Sclerotia A hardened granulated structure formed by a compact mass of fungal mycelium with the ability to survive under some extreme environmental conditions.

Vegetative incompatibility A cell-death reaction occurs between two genotypically distinct fungal species or isolates, and mostly resulting in failed transmission of viruses via anastomosis.

Introduction

The first botybirnavirus, *Botrytis porri* botybirnavirus 1 (BpBV1), was identified in the phytopathogenic fungus *Botrytis porri*, as a causal agent of hypovirulence of *B. porri*. BpBV1-infected *B. porri* strains showed dramatically impaired mycelial growth and virulence, and formed numerous mycelial sectors at the colony margin (Fig. 1). Two dsRNA segments (the genome of BpBV1) of approximately 6.2 and 5.8 kbp in size together with the spherical virions were detected in the virus-infected isolate GarlicBc-72. BpBV1 is able to be efficiently transmitted via conidia, and can also be horizontally transferred to other *B. porri* isolates through anastomosis. However, the horizontal transmission seems to be limited by vegetative incompatibility.

Since the firstly discovery of botybirnavirus, botybirnaviruses were soon reported in the close relative of *Botrytis*, *Sclerotinia sclerotiorum*. The infection of botybirnaviruses was determined to be close associated with the hypovirulence of *S. sclerotiorum* as well. Recently, more candidate members in the genus of *Botybirnavirus*, were detected in the fungi of Ascomycota, like fungi of genera *Alternaria* and *Bipolaris*. With the development of sequencing technology, more botybirnavirus-like sequences were also identified during the metatranscriptomic analysis, such as the funding of botybirnavirus-like sequences in the metatranscriptomics survey of soybean phyllosphere phytobiomes. Therefore, botybirnaviruses may have a wide distribution among different fungal groups.

Virion Properties

Electron microscope observation of negative stained botybirnavirus virions (BpBV1) with aqueous uranyl acetate showed that they are spherical in shape, of approximately 35–40 nm in diameter, and probably non-enveloped (Table 1, Fig. 2). At least two structural proteins (SPs) are identified for the BpBV1 virions, encoded by the two dsRNA segments, respectively. Like viruses in *Chrysoviridae* and *Partitiviridae*, the two dsRNAs of BpBV1 are thought to be separately encapsidated in separate virus particles because the virus particles might not be spacious enough for simultaneous packaging of the two dsRNAs. Moreover, variable and unequal molar ratios of two dsRNA segments in purified virus particles of *Sclerotinia sclerotiorum* botybirnavirus 1 (SsBV1) also support the idea that the two segments of botybirnaviruses are separately packaged into particles.

Genome Organization and Replication

The genomes of botybirnaviruses comprise two dsRNAs. The larger dsRNA of BpBV1 is 6215 bp (dsRNA-1, GenBank accession no. JF716350) in length while the size of smaller dsRNA is 5879 bp (dsRNA-2, GenBank accession no. JF716351). The two segments show high sequence identity (~95%) at the 5' termini (500 bp), including the 5'-untranslated regions (UTRs) and partial coding region (Fig. 3). Each dsRNA segment of BpBV1 possesses a large open reading frame (ORF), designated as ORF I (on dsRNA-1) and ORF II (on dsRNA-2) (Fig. 3). The protein encoded by the 5'-proximal coding region of ORF I and ORF II have been determined to be the SPs through peptide mass fingerprinting (PMF) analysis. The protein encoded by the 3'-proximal coding region of ORF I encompasses the RdRp_4 conserved domain sequence (pfam02123 in the conserved domain database of NCBI) and shows

Fig. 1 Colony morphology of the *Botrytis porri* botybirnavirus 1 (BpBV1)-transfected isolate 38T (left) and the BpRV1-free strain GarlicBc-38 (right) on potato dextrose agar (20°C, 15 days).

Table 1 Virion properties of different botybirnaviruses

<i>Virus name</i>	<i>Shape</i>	<i>Diameter (nm)</i>	<i>Genome size (bp)</i>	<i>Genbank Acc. No.</i>
<i>Botrytis porri</i> botybirnavirus 1	spherical	35	6215, 5879	JF716350, JF716350
<i>Sclerotinia sclerotiorum</i> botybirnavirus 1	spherical	38	6457, 5965	KP774592, KP774593
<i>Sclerotinia sclerotiorum</i> botybirnavirus 2	spherical	40	6159, 5872	KT962972, KT962973

sequence similarity with RdRp encoded by viruses in the families *Totiviridae*, *Chrysoviridae*, *Quadriviridae*, and *Megabirnaviridae*. In addition, the proteins encoded by the 5'-proximal region of ORF I and by the entire ORF II lack significant sequence similarities to the proteins of any other known virus groups. SsBV1, a member of a tentative species of the genus *Botyvirus*, has a third dispensable satellite-like dsRNA (SatlRNA) element of ~1.7 kbp (GenBank accession no. KP774594). The expression strategy of botybirnaviruses and functions of remaining regions of the two deduced polyproteins remain unclear. The amino acid sequences of the two SPs also show a significant similarity with each other. Interestingly, whether phylogeny is analyzed based on either of the two SP, their tree topology is similar. This suggests that the ancestral botybirnavirus might have undergone a single duplication event of the SP coding domain.

Taxonomy and Similarity With Other Viruses

Botybirnaviruses are phylogenetically more closely related to viruses of the families *Totiviridae* and *Quadriviridae* than to viruses of the families *Chrysoviridae* and *Megabirnaviridae* based on the RdRp₄ conserved domain sequence similarity and phylogenetic analysis (Fig. 4). The family name, *Botybirnaviridae*, was initially proposed to the International Committee of Taxonomy of Viruses

Fig. 3 Genome organization of *Botrytis porri* botybirnavirus 1 (BpBV1). The genome possesses two dsRNA segments, dsRNA-1 and dsRNA-2. The dsRNA-1 is 6215 bp long and comprises one large ORF (nt positions 404–6112), encoding a polyprotein of 1902 aa. The dsRNA-2 is 5788 bp long and also comprises one large ORF (nt positions 405–5771), which encodes a polypeptide of 1788 aa. p70 and p85/80 are the structural proteins of BpBV1 inferred from peptide fingerprinting analyses. Highly-conserved region (~500 bp) covering the entire 5'-UTR and partial coding region are highlighted in red on the BpBV1 genome.

(ICTV) to accommodate the genus *Botybirnavirus* including four species (Table 1). The viruses belonging to the proposed family can be clearly separated from other viruses with bipartite genomes based on bipartite genome size (~12 kbp, which is smaller than that of *Megabirnaviridae* (~17 kbp) but larger than those of *Partitiviridae* (~3–4.8 kbp), *Picobirnaviridae* (~4 kbp) and *Birnaviridae* (~6 kbp)), genome organization and nucleotide and amino acid sequence similarity of encoded RdRp and CP sequences. The current taxonomic status of botybirnaviruses, approved by ICTV, is that *Botrytis porri* botybirnavirus 1 is only the species in the genus *Botybirnavirus* which is as yet unassigned to a family.

Transmission and Distribution

There are no known natural vectors for the transmission of botybirnaviruses. Under laboratory conditions, the transmission of BpBV1 is similar to most mycoviruses, vertically through sporulation or horizontally by hyphal anastomosis between somatically compatible fungal strains. The vertical transmission via sporulation for BpBV1 is highly efficient in *B. porri* strain GarlicBc-72. BpBV1 could be detected in 34 out of 35 single-conidium (SC) isolates of strain GarlicBc-72 with the vertical transmission rate of 97.1%. In contrast, the horizontal transmission of BpBV1 was not so efficient, it could only be transmitted from strain GarlicBc-72 to one of the recovered SC isolate SC35 but failed to be transmitted to other two strains of *B. porri* during the in-laboratory test. This might be due to the vegetative incompatibility among different *B. porri* strains. As isolate SC35 is isogenic to strain GarlicBc-72, they should be vegetatively compatible to each other resulting in successful viral transmission between the two individuals. Similar unsuccessful horizontal transmission was also observed for *Sclerotinia sclerotiorum* botybirnavirus 2 (SsBV2), and may also be caused by the vegetative incompatibility between the donor and recipient *S. sclerotiorum* strains. Although in-laboratory tests showed the horizontal transmission of BpBV1 was limited, it is surprising that the same botybirnavirus, BpBV1, was detected in both *B. squamosa* and *S. sclerotiorum* in addition to *B. porri*. Moreover, recent results from high through-put sequencing also indicate that BpBV1 may be present in the population of *B. cinerea*. This suggests that interspecific transmission of BpBV1 may occur in field conditions without the limitation by vegetative incompatibility among different fungal species, although the underlining mechanism is still unclear. Botybirnaviruses probably have a wide host range, mainly infecting ascomycetes including *B. porri*, *B. squamosa*, *S. sclerotiorum*, *B. maydis*, and *Alternaria*. Besides being detected in population of *B. porri* and *B. squamosa* of China, high through-put sequencing data also showed that botybirnaviruses were also present in soybean leaf samples from United States and BpBV1 was also found in the *S. sclerotiorum* population of Australia, indicating BpBV1 and other botybirnaviruses may have a geographic distribution all over the world.

Biology

BpBV1 was reported to confer hypovirulence on the phytopathogenic fungus *B. porri*, the causing agent of garlic clove rot, garlic leaf blight, and leek leaf rot. Compared with BpBV1-free isolates of *B. porri*, the BpBV1-infected isolate grew slowly on potato dextrose agar, formed numerous mycelial sectors at the colony margin and caused smaller lesions on leaves of garlic (*Allium sativum*). In addition, abundant vacuole-like membranous structures and membranous vacuoles/vesicles were observed in the cytoplasm of virus-infected isolate. Three lines of experimental evidence support the conclusion that BpBV1 is responsible for the reduced mycelial growth and hypovirulence in *B. porri*. The first clue is based on the vertical transmission experiment. All BpBV1-infected SC isolates of strain GarlicBc-72 were hypovirulent and accompanied with reduced mycelial growth. In contrast, the BpBV1-free SC isolate SC35 became virulent on garlic leaves and grew normally. Secondly, after BpBV1 was transmitted to the virus cured strain SC35 through hyphal contact, three derivative isolates of strain SC35 carrying BpBV1 showed reduced mycelial

Fig. 4 Phylogenetic analysis of *Botrytis porri* botybirnavirus 1 and other 21 selected RNA viruses presented in an neighbor-joining (NJ) tree inferred from the RdRp sequences. The NJ tree was constructed by using the CLUSTAL_W program in the MEGA 6.0 software. The number labeled at each node indicates the bootstrap percentage ($N = 1000$). Abbreviated virus names and GenBank accession number for viral RdRp: SsRV1, *Sphaeropsis sapinea* RNA virus 1 (NC_001963); HvV190S, *Helminthosporium victoriae* virus 190S (U41345); LRV-1-1, *Leishmania* RNA virus 1-1 (M92355); LRV-2-1, *Leishmania* RNA virus 2-1 (U32108); TVV1-1, *Trichomonas vaginalis* virus 1-1 (U08999); TVV2-1, *Trichomonas vaginalis* virus 2-1 (AF127178); UmVH1, *Ustilago maydis* virus H1 (NC_003823); ScV-L-A, *Saccharomyces cerevisiae* virus L-A (J04692); ScV-L-BC, *Saccharomyces cerevisiae* virus L-BC (U01060); RnQV1-W1075, *Rosellinia necatrix* quadrivirus 1-W1075 (AB620063); RnQV1-W1118, *Rosellinia necatrix* quadrivirus 1-W1118 (AB744679); BpBV1, *Botrytis porri* botybirnavirus 1 (JF716350); SsBV1, *Sclerotinia sclerotiorum* botybirnavirus 1 (KP774592); SsBV2, *Sclerotinia sclerotiorum* botybirnavirus 2 (KT962972); ABV1, *Alternaria botybirnavirus* 1 (KX784491); BmBV1, *Bipolaris maydis* botybirnavirus 1 (MF034087); PCV, *Penicillium chrysogenum* virus (AF296339); HvV145S, *Helminthosporium victoriae* virus 145S (AF297176); RnMBV1-W779, *Rosellinia necatrix* megabirnavirus 1-W779 (AB512282); SsMBV1, *Sclerotinia sclerotiorum* megabirnavirus 1 (KP686398); AHV, *Atkinsonella hypoxylon* virus (L39125); WcCV1, *White clover* cryptic virus 1 (AY705784).

growth and impaired virulence on garlic leaves. The transfection experiment provided the third evidence, in which the purified BpBV1 particles were introduced into the protoplasts of the BpBV1-free virulent strain GarlicBc-38 of *B. porri* artificially. The derivative isolate 38T also displayed debilitation symptoms (Fig. 1), including reduced mycelial growth and hypovirulence on garlic leaves. It is interesting that although BpBV1 caused severe debilitation on *B. porri*, the effects of BpBV1 on *B. squamosa* seems to be mild. Only slightly reduced mycelial growth and virulence on garlic leaves was observed on the BpBV1-infected *B. squamosa* strain. Whether this phenomenon was caused by the minor sequence differences between the two BpBV1 strains from *B. porri* and *B. squamosa*, or the different genetic background of the two hosts remain to be investigated.

Similarly, the infection of botybirnaviruses in *S. sclerotiorum* is also able to reduce its mycelial growth and virulence. The hypovirulent *S. sclerotiorum* strain AH16 was infected by SsBV2 together with a mitovirus (*Sclerotinia sclerotiorum* mitovirus 4, SsMV4). To test whether SsBV2 or/and SsMV4 is responsible for the hypovirulence of strain AH16, both viruses were tested to be transmitted from strain AH16 to Ep-1PNA367R via hyphal contact, or to be eliminated from strain AH16 through protoplast regeneration. Nevertheless, due to the vegetative incompatibility between the donor strain and the recipient strain, the transmission was failed. Moreover, the protoplast regeneration was also unable to cure the virus in strain AH16. Finally, the virions of SsBV2 was successfully introduced into strain Ep-1PNA367R. The results based on dsRNA extraction, or RT-PCR detection revealed that the transfectant Ep-1PNA367RVT carried SsBV2 without the presence of SsMV4. Compared with SsBV2-free strain Ep-1PNA367R, strain AH16 grew slower and showed reduced virulence on detached soybean leaves. In addition, strain Ep-1PNA367R formed sclerotia at

7 days post inoculation (dpi), whereas strain AH16 formed fewer and smaller sclerotia at 15 dpi. It is noteworthy that strain Ep-1PNA367RVT showed more severely debilitated symptoms compared with strain AH16, including slower mycelial growth, more impaired virulence and no sclerotial production. In addition, SsBV2 was able to transmit from strain Ep-1PNA367RVT to SsBV2-free strain Ep-1PNA367, and the newly SsBV2-infected strain exhibited similar biological traits to those of Ep-1PNA367RVT. Therefore, based on these observations, SsBV2 confers hypovirulence to *S. sclerotiorum*. In contrast, infection of SsBV1 alone has no significant impacts on culture morphology and virulence of *S. sclerotiorum*. However, infection of SsBV1 along with its SatlRNA leads to slightly reduced virulence and slower mycelial growth rate on its host. Nevertheless, the culture morphology and sclerotial formation of strains carrying both SsBV1 and SatlRNA was comparable to those of strains without the infection by both SsBV1 and SatlRNA, or by SsBV1 alone. Besides *Botrytis* spp. and *S. sclerotiorum*, botybirnaviruses were also reported in the fungi *B. maydis* and *Alternaria*. Although the genomes of those two botybirnaviruses were fully sequenced, the impacts on their fungal hosts are still unknown.

Anastomosis The fusion between branches of hyphae.

Conidium Asexual spore of a fungus.

Heterokaryon A multinucleate fungal cell that contains genetically different nuclei.

Introduction

Chrysoviruses were initially discovered in the late 1960s and early 1970s, when the presence of isometric virus particles in many industrial strains of the ascomycete *Penicillium chrysogenum* used for penicillin production was noted. Virus infection was considered to be responsible for the instability of some of these strains, generating significant interest in the study of *Penicillium* viruses. *Penicillium chrysogenum* virus (PcV), the exemplar virus of the genus *Alphachrysovirus*, was one of the first mycoviruses subjected to extensive biochemical, biophysical and structural studies. PcV and the related viruses *Penicillium brevi-compactum* virus (PbV) and *Penicillium cyaneo-fulvum* virus (Pc-fV) have similar isometric particles, 35–40 nm in diameter, and are serologically related. These virus properties were undisputed in these initial studies, however there was confusion as to whether these viruses contain three or four double-stranded (ds) RNA segments. Because none of these three *Penicillium* viruses were characterized at the molecular level, they were originally grouped under the genus *Chrysovirus* and provisionally placed in the family *Partitiviridae* with the assumption that their genomes were bipartite, with dsRNA 1 encoding the RNA-dependent RNA polymerase (RdRp) and dsRNA 2 encoding the major capsid protein (CP). Additional dsRNAs found in these isolates were nominated dsRNA 3 and 4 and were presumed to represent defective or satellite dsRNAs as described for some partitiviruses. Determination of the complete nucleotide sequence and genome organization of each of the four monocistronic dsRNA segments associated with PcV virions together with another chrysovirus *Helminthosporium victoriae* virus 145S (HvV145S) in the early 2000s led to a reconsideration of the classification of the genus *Chrysovirus*. Based on the consistent and simultaneous presence of four dsRNA segments, the existence of extended regions of highly conserved terminal sequences at both ends of the four segments, together with sequence comparisons and phylogenetic analysis, it became clear that PcV and related viruses should not be classified with the family *Partitiviridae*. These observations led to the creation of a new family the *Chrysoviridae* to accommodate isometric dsRNA mycoviruses with multipartite genomes. The name *chryso* means *gold* in Greek and is derived from the specific epithet of *P. chrysogenum*, the fungal host of the prototype strain of the type species, (PcV), which often produces a golden yellow pigment. More recently, the discovery and characterization of a large number of chrysovirus-related viruses resulted in a reorganization of the *Chrysoviridae* family: the original genus *Chrysovirus* was renamed as *Alphachrysovirus* and a new genus *Betachrysovirus* was created with *Botryosphaeria dothidea chrysovirus 1* as the type species. The two genera accommodate viruses that possess three to seven genomic segments and are not only present in ascomycetes and basidiomycetes but also associated with plants and insects.

Virion Properties

Virions of members in the family *Chrysoviridae* are isometric, proteinaceous in nature with no envelope and are 35–40 nm in diameter. The buoyant densities of the virions are in the range of 1.34–1.39 g cm⁻³ and their sedimentation coefficients (in Svedberg units) are in the range of 145S to 150S. Generally, each virion contains only one genomic dsRNA segment, however, purified preparations of PcV and Pc-fV can contain minor distinctly sedimenting components that include empty particles and replication intermediates. Chrysovirus particles possess virion-associated RdRp activity, which catalyzes the synthesis of single-stranded (ss) RNA copies of the (+) strand of each of the genomic dsRNA molecules. *In vitro* transcription occurs by a conservative mechanism, whereby the released ssRNA represents the newly synthesized (+) strand.

[☆]This work is dedicated to the memory of our friend and colleague Said Ghabrial, who sequenced the first chrysovirus in 2000 and passed away in November 2018.

[†]Deceased.

Virion structure and composition

The three-dimensional structure and protein stoichiometry of several chrysoviruses has been analyzed by three-dimensional cryo-electron microscopy (3D cryo-EM) combined with analytical ultracentrifugation analysis. The 3D cryo-EM structures of two chrysoviruses, PcV and *Cryphonectria nitschkei* chrysovirus virus 1 (CnCV1), were determined at sub-nanometer and near-atomic resolutions, respectively.

Virions are isometric, non-enveloped, about 40 nm in diameter with a ~ 50 Å thick protein shell. The capsids of PcV and CnCV1 comprise 60 copies of a 982- and 902-amino acid (aa) polypeptide, respectively, arranged on an authentic T=1 icosahedral lattice. The most prominent features are 12 outwardly protruding pentons, each containing five copies of the CP (Fig. 1(a)). The uneven outer surface is similar to the capsid of *Saccharomyces cerevisiae* virus L-A (ScV-L-A; a totivirus with an undivided genome), and contrasts with the smooth outer surface of reoviruses, where the CP has a plate-like structure.

PcV and CnCV1 capsids constitute partial exceptions to the most extended tendency among dsRNA viruses, the T=1 core with 60 equivalent dimers. The PcV CP is formed by a repeated predominantly α -helical domain, indicative of ancestral gene duplication. These two domains are arranged in two sets of five: five A domains directly surround the icosahedral fivefold axis and five B domains intercalated between them, forming a pseudodecamer. This organization with two similar motifs generates an architecture resembling that of the 120-subunit T=1 lattice of totivirus, reovirus, and cystovirus capsids, in which the two asymmetrical dimer components are arranged in a near-parallel fashion. A 120-subunit (or 120-domain) T=1 layer, which remains structurally undisturbed throughout the viral cycle, is therefore a ubiquitous architecture for management of dsRNA metabolism.

The near-atomic cryo-EM structure of the PcV virion at ~ 4 Å resolution shows that the complete 982-aa CP is built of 33 α -helices and 20 β -strands (Fig. 1(b)). The CP has two domains or halves with a very similar fold, an N-terminal domain (residues 1–498) connected by a 16-residue linker to a C-terminal domain (516–982) (Fig. 1(c)). Both PcV CP domains have a long (> 30 Å) α -helix tangential to the capsid surface (Fig. 1(b); arrows). Despite the lack of sequence similarity between the two halves, the CP is an almost perfect structural duplication of a single domain in which many α -helices and β -chains show good matching (Fig. 2(a)). Superimposition of secondary structure elements shows, in addition to the N- and C-terminal arms, a single “hot spot” on the outer capsid surface into which structural and functional variations can be introduced by insertion of 50–100 residue segments (Fig. 2(b)). A preferential insertion site would allow the acquisition of new functions (e.g., new enzymatic activities) while preserving basic capsid protein folding. Notably, the basic PcV fold is well preserved among dsRNA viruses, and provides information regarding the progenitor fold of the dsRNA virus lineage and its evolutionary mechanisms. Structural comparisons of either of the PcV domains and the ScV-L-A or *Rosellinia necatrix* quadrivirus 1 (RnQV1) CPs highlight the same conserved PcV motif and the hot spot for insertions, in addition to two additional insertion zones that face the outer capsid surface (Fig. 2(b) and (c)). This co-localization suggests that these preferential insertion sites are ancient. Structural comparison of PcV and other dsRNA viruses in the family *Reoviridae* shows ancestral structural motifs or subdomains that have acted as a skeleton.

Fig. 1 Three-dimensional cryo-EM reconstruction of *Penicillium chrysogenum* virus (PcV) virions at ~ 4 Å resolution. (a) Superimposed N-terminal (blue) and C-terminal (yellow) domains of the PcV CP (non-superimposed regions are white). (b) Sequence alignment of N- and C-terminal domains resulting from the structural alignment. α -helices (rectangles) and β -strands (arrows) are rainbow-colored from blue (N terminus) to red (C terminus) for each domain. Triangles represent non-aligned segments (sizes indicated). (c) Structural alignment of the PcV CP N-terminal domain (blue) with L-A capsid protein (red).

Whereas dsRNA in the interior of reovirus cores is very compact (with an average genome density of 40 bp/100 nm³ and a spacing among dsRNA strands of 25–30 Å), PcV and CnCV1 have spacious capsids. Considering the volume available in the capsid interior and average genome size of 3200 bp (each segment is separately encapsidated in a similar particle), the packed dsRNA would have an interstrand spacing of 40 Å, which closely matches the relatively low density in most fungal virus capsids. The looser packing of the dsRNA would probably improve template motion in the transcriptional and replicative active particle that contains 1–2 copies of the RdRp. Although most mycovirus T=1 capsids are negatively charged on their inner surface, the PcV CP inner surface has highly positively charged triskelion-shaped areas that maintain the encapsidated genome in close contact with the inner capsid surface. This arrangement of dsRNA might further facilitate genome mobility within the capsid, and/or have a structural role in capsid stability. The capsid is highly porous; whereas the ~11 Å diameter pores at the fivefold axis would allow the exit of viral transcripts but not of dsRNA, the ~5 Å-diameter pores at the threefold axis would allow nucleotide diffusion.

Genome Organization

The virions of members of family *Chrysoviridae* contain three to seven unrelated linear, separately encapsidated, monocistronic dsRNA segments 0.8–3.7 kbp in size (Table 1); the genomic structures of PcV, the prototype of genus *Alphachrysovirus*, and

^alength of dsRNA is underestimated because only partial sequence is available.

Botryosphaeria dothidea chrysovirus 1 (BdCV1), the prototype of genus *Betachrysovirus*, each comprising four dsRNA segments, are schematically represented in Fig. 3.

For the genus *Alphachrysovirus*, the largest segment, dsRNA 1, encodes the RdRp and the second largest segment, dsRNA 2, encodes the major CP. The earlier conflicting reports on whether PcV contains three or four segments were explained when studies on cDNA cloning and sequencing of the viral dsRNAs were completed, revealing that dsRNAs 3 and 4 only differ in size by 74 bp (Table 1) and co-migrate when separated by agarose gel electrophoresis. Previous studies on sequencing analysis and *in vitro* coupled transcription-translation assays showed that each of the four dsRNAs is monocistronic, as each dsRNA contains a single major open reading frame (ORF) and each is translated into a single major product of the size predicted from its deduced aa sequence. Therefore, the fact that PcV virions contain four distinct dsRNA segments was clearly established. Unlike PcV, HvV145S dsRNAs 3 and 4 are clearly resolved from each other when purified dsRNA preparations are subjected to agarose gel electrophoresis and, as shown in Table 1, are significantly different in size. Assignment of numbers 1–4 to PcV dsRNAs was made according to their decreasing size. Following the same criterion as used for PcV, the dsRNAs associated with all members of the genus *Alphachrysovirus* were assigned the numbers 1–4. Sequence comparisons, however, indicated that dsRNA 3 of HvV145S, Amasya cherry disease associated chrysovirus (ACDACV) and *Macrophomina phaseolina* chrysovirus 1 (MpCV1) are in fact the counterparts of PcV dsRNA 4 rather than dsRNA 3. Likewise, dsRNA 4 of these three chrysoviruses are the counterparts of PcV dsRNA3. Since PcV was

Fig. 3 Schematic representation of the genomic organization of *Penicillium chrysogenum* virus (PcV), exemplar virus for the type species of genus *Alphachrysovirus*, and *Botryosphaeria dothidea* chrysovirus 1 (BdCV1), exemplar virus for the type species of genus *Betachrysovirus*. Each genome consists of four dsRNAs, each containing one open reading frame (ORF; colored boxes) flanked by 5'- and 3'-untranslated regions (UTRs; black double lines). The light colored box in dsRNA 1 represents the RdRP₄ motif; the dark colored box in dsRNA 1 represents an independent P-loop NTPase domain predicted by HHpred; the gray colored thick lines represent a region of homology between the proteins encoded by dsRNAs 1 and 3.

the first chrysovirus to be characterized at the molecular level and to avoid confusion, the protein designations P3 and P4 as used for PcV were adopted and referred to as alphachryso-P3 and alphachryso-P4. Therefore, whereas the alphachryso-P3 protein represents the gene product of PcV dsRNA 3, it comprises the corresponding gene product of, for instance, HvV145S dsRNA4. Additionally, some members of the genus *Alphachrysovirus*, including *Brassica campestris* chrysovirus 1 (BcCV1), *Colletotrichum gloeosporioides* chrysovirus 1 (CgCV1), *Fusarium oxysporum* chrysovirus 1 (FoCV1), *Persea americana* chrysovirus (PaCV), and *Raphanus sativus* chrysovirus 1 (RsCV1) appear to have only 3 dsRNA segments, lacking the dsRNA encoding the alphachryso-P3 protein.

Regarding members of the genus *Betachrysovirus*, the RdRp is encoded by the largest segment, dsRNA 1, while the major CP is usually encoded by dsRNA 2, but it may also be encoded by dsRNA 3, in the case of *Fusarium graminearum* dsRNA mycovirus 2 (FgV2) and *Fusarium oxysporum* f. sp. *dianthi* mycovirus 1 (FodV), or dsRNA 4, in the case of *Magnaporthe oryzae* chrysovirus 1-A (MoCV1-A). It should be noted that betachrysovirus CPs share no detectable homology with alphachrysovirus CPs. Similarly to the approach used for alphachrysoviruses, the betachrysovirus proteins encoded by dsRNA 3 and 4 of the exemplar virus BdCV1 were designated as betachryso-P3 and betachryso-P4, respectively, and are not necessarily produced by dsRNA 3 and 4 of all known betachrysoviruses. For instance, MoCV1-A dsRNA 2 encodes betachryso-P3, while dsRNA 3 encodes betachryso-P4. Unlike alphachrysoviruses, no betachrysoviruses with 3 genomic segments have been reported; however, betachrysoviruses with five genomic segments, such as MoCV1-A, FgV2 and *Alternaria alternata* chrysovirus 1 (AaCV1), and one Betachrysovirus with 7 genomic segments, *Colletotrichum fruticola* chrysovirus 1 (CfCV1), has been described.

Although the proteins alphachryso-P3 and alphachryso-P4, encoded by PcV dsRNA 3 and dsRNA 4, respectively, are of unknown function, protein database searches reveal that PcV alphachryso-P3 sequence shares a 'phytoreo S7 domain' with a family consisting of several phytoreovirus P7 proteins known to be viral core proteins with nucleic acid binding activities (see below). The PcV alphachryso-P4 (and comparable proteins of other alphachrysoviruses) contains the motifs that form the conserved core of the ovarian tumor gene-like superfamily of predicted cysteine proteases. In contrast, little is known about the possible functions of the betachryso-P3 and betachryso-P4 proteins which share no homology with the alphachryso-P3 and alphachryso-P4 proteins or the betachrysoviruses proteins encoded by the dsRNAs 5–7.

The majority of the 5'- and 3'-untranslated regions (UTRs) of chrysovirus dsRNAs are relatively long, up to 698 nt and 865 nt, respectively (Table 1). The longest 5'-UTR belongs to CnCV1 dsRNA 4, while the longest 3'-UTR belongs to MoCV1-A dsRNA 5. The only 5'-UTR shorter than 50 nt belongs to dsRNA 1 of the insect-associated Shuangao chryo-like virus (SCLV). Both PcV (alphachrysovirus) and BdCV1 (betachrysovirus) UTRs have strictly conserved 5'- and 3'-termini (Fig. 4) and there appear to be some sequence similarity between them; for instance the poly A sequence at the 5'-terminus or the 'GUGU' sequence at the 3'-terminus. In addition, a 40–75 nt region with high sequence identity is present in the 5'-UTR of all four PcV dsRNAs. A second region of strong sequence similarity is present immediately downstream, which consists of a stretch of 30–50 nt containing a reiteration of the sequence 'CAA'. The (CAA)_n repeats are found to a lesser extent in the 5'-UTRs of BdCV1 and are similar to the enhancer elements present at the 5' UTRs of tobamoviruses.

Fig. 5 Comparison of the eight conserved motifs of all chrysovirus RdRps presented in Table 1. Numbers in parentheses correspond to amino acid residues present between the motifs. Asterisks and colons respectively signify identical and highly conserved amino acid residues at the positions indicated.

Genome Expression and Replication

Chrysovirus RdRps

The largest dsRNA segment (dsRNA 1) of all chrysoviruses so far sequenced contains a single large ORF encoding the RdRp. The molecular mass of chrysovirus RdRps ranges from 110 to 131 kDa (Table 1). These values are consistent with those estimated by SDS-PAGE of the *in vitro* translation products of full-length transcripts derived from both PcV and Hv145SV dsRNA 1 cDNAs. Examination of the deduced amino acid sequence of the RdRp ORF reveals the presence of the eight conserved motifs characteristic of RdRps of dsRNA viruses present in simple eukaryotes (Fig. 5). Additionally, there is an independent P-loop NTPase domain at the N-terminus of alphachrysovirus and betachrysovirus RdRps as shown by HHpred, a remote protein homology detection software. In the case of alphachrysoviruses this domain overlaps with a region homologous to alphachryso-P3. Members of the P-loop NTPase domain superfamily are characterized by conserved nucleotide phosphate-binding motifs, also referred to as the Walker A motif (GxxxxGK[S/T]) and the Walker B motif (hhhh[D/E], where h is a hydrophobic residue).

Chrysovirus CPs

The second largest dsRNA segment (dsRNA 2) of alphachrysoviruses currently sequenced contains a single large ORF encoding the CP, while the CP of betachrysoviruses currently sequenced may also be produced by dsRNA 3 or 4. The molecular mass of chrysovirus CPs ranges from 80 to 126 kDa (Table 1). The predicted size of PcV CP (109 kDa) is similar to that estimated by

SDS-PAGE of purified PcV virions as well as that determined for the *in vitro* translation product of a full-length transcript of dsRNA 2 cDNA. Direct evidence that dsRNA 2 of both the alphachrysovirus PcV and the betachrysovirus BdCV1 encodes CP was provided by amino acid sequencing of a tryptic peptide derived from a gradient-purified PcV capsid.

Alphachryso-P3 Shares a 'Phytoreo S7 Domain' With Core Proteins of Phytoreoviruses

DsRNA 3 of PcV, *Aspergillus fumigatus* chrysovirus (AfuCV), *Isaria javanica* chrysovirus 1 (IjCV1), and *Verticillium dahliae* chrysovirus 1 (VdCV1) encodes the alphachryso-P3 protein, whereas dsRNA 4 of Hv145SV, ACDACV, and MpCV1 encodes the corresponding alphachryso-P3. Although the function of alphachryso-P3 is not known, sequence analysis and database searches offer some clues. ProDom database searches reveal that chryso-P3 sequences share a 'phytoreo S7 domain' with a family consisting of several phytoreovirus P7 proteins known to be viral core proteins with nucleic acid binding activities. The consensus for the three chrysoviruses is [X(V/I)V(M/L)P(A/M)G(C/H)GK(T/S)T-(L/I)]. Phytoreovirus P7 proteins bind to their corresponding P1 (transcriptase/replicase) proteins, which bind to the genomic dsRNAs. It is of interest, in this regard, that the N-terminal regions of all alphachryso-P3s (encompassing the amino acids within positions 1–500) share significant sequence similarity with comparable N-terminal regions of the putative RdRps encoded by chrysovirus dsRNA1s. The regions in the dsRNA 1-encoded proteins with high similarity to alphachryso-P3 occur upstream of the eight highly conserved motifs characteristic of RdRps of dsRNA viruses of simple eukaryotes. The significance of this sequence similarity to the function of alphachryso-P3 is not known for certain, but one may speculate that the N-terminal region of these proteins might play a role in viral RNA binding and packaging. In contrast, betachryso-P3 shares no detectable homology with alphachryso-P3, contains no phytoreo S7 domain and has no similarity with the betachrysovirus RdRps.

Chryso-P4 is a Putative Protease and Virion Associated as a Minor Protein

Present evidence, based on amino acid sequencing of a tryptic peptide derived from gradient-purified PcV virions, strongly supports the conclusion that PcV alphachryso-P4 is a virion-associated minor protein. Additionally, alphachryso-P4 encoded by some chrysoviruses contains the motif PGDGXCXXHX. This motif (I), along with motifs II (with a conserved K), III, and IV (with a conserved H), form the conserved core of the ovarian tumor gene-like superfamily of predicted cysteine proteases. Multiple alignments showed that motifs I–IV are also present in other viruses including *Agaricus bisporus* virus 1, a tentative member of the family *Chrysoviridae*. Whether the RNAs of these viruses indeed code for the predicted proteases remains to be investigated.

Replication of Chrysoviruses

There is very limited information on how chrysoviruses replicate their dsRNAs. The virion-associated RdRp catalyzes *in vitro* end-to-end transcription of each dsRNA to produce mRNA by a conservative mechanism. Purified virions containing both ssRNA and dsRNA have been isolated from *Penicillium* spp. infected with PcV or Pc-fV and may represent replication intermediates.

Taxonomy and Phylogenetic Analysis

The *Penicillium* chrysoviruses PcV, Pc-fV, and PbV are serologically related and have similar biochemical and biophysical properties. Although molecular data is only available for PcV, the three viruses could be considered as strains of the same virus for all practical purposes. The fact that these closely related viruses occur in different fungal species suggested that transmission by means other than anastomosis may occur naturally, since heterokaryon formation between different fungal species is unlikely. Horizontal transmission of fungal viruses in nature however, has yet to be demonstrated and in the case of viruses of *Penicillium* spp. may not need to occur since the viruses replicate in parallel with their hosts and are carried intracellularly during vegetative growth of the host. Furthermore, the viruses are efficiently disseminated by vertical transmission *via* the conidia of *Penicillium* spp. It seems feasible, however, that virus infection arose early in the phylogeny of *P. brevi-compactum*, *P. chrysogenum*, and *P. cyaneo-fulvum* before they diverged and that the resident virus remained associated with them during their subsequent evolution.

BLAST searches of chrysovirus RdRp amino acid sequence showed significantly high sequence similarity with the RdRps of several members of the family *Totiviridae*. Interestingly, no significant hits were evident with any of the viruses in family *Partitiviridae*, another validation for the removal of chrysoviruses from the family *Partitiviridae* and their placement in the newly created family *Chrysoviridae*. The conclusion that chrysovirus RdRps are more closely related to those of totiviruses than to those of partitiviruses is supported by published results of phylogenetic analysis of RdRp conserved motifs and flanking sequences of chrysoviruses and viruses in families *Totiviridae* and *Partitiviridae* and comparisons of the conserved motifs of chrysovirus RdRps with those of totiviruses and partitiviruses. For instance, the database Pfam, which includes annotations and multiple sequence alignments generated using hidden Markov models, classifies chrysovirus and totivirus RdRps in of the protein family RdRp_4 (PF02123), while partitivirus RdRps belong to RdRp_1 (PF00680).

The recent discoveries of new viruses related to chrysoviruses have led to an expansion and reorganization of the family *Chrysoviridae*. The family has now two genera, *Alphachrysovirus* and *Betachrysovirus*, accommodating seventeen and eight species

Fig. 6 Maximum likelihood phylogenetic tree created based on the RdRp sequences of chrysoviruses. The sequences were aligned with MUSCLE as implemented by MEGA 6, all positions with less than 30% site coverage were eliminated and the LG + G + I + F substitution model was used. At the end of the branches, blue circles indicate that the virus infects fungi; green circles indicate that the virus infects or is associated with plants; red circles indicate that the virus infects or is associated with insects. *Saccharomyces cerevisiae* virus L-A (ScV-L-A), a member of the genus *Totivirus*, family *Totiviridae*, was used as the outgroup.

respectively, based on the formation of two distinct clades as evidenced by phylogenetic analysis (Fig. 6). The analysis was based on the sequence of chrysovirus RdRp, which is the only protein with detectable homology among all viruses belonging to the two genera. The rest of the viral proteins, including the CP, are conserved within but not among genera. The one exception is SCLV, an insect-associated virus belonging to the genus *Alphachrysovirus*, whose proteins, the RdRp notwithstanding, are non-homologous to those of the other members of genus *Alphachrysovirus* or *Betachrysovirus*.

An interesting feature of chrysoviruses is a variability in the number of their genomic segments, which range from three to seven. More specifically, the known members of the genus *Alphachrysovirus* can have three or four segments as their genome. Six members of the genus *Alphachrysovirus* have three genomic segments and most of them infect or are associated with plants. Therefore alphachryso-P3 is not necessary for virus replication, at least under certain conditions that have not been characterized yet. Additionally, since FoCV1 alphachryso-P4 appears to be non-functional due to the presence of nonsense mutations in the open reading frame, it is feasible that the replication cycle of chrysoviruses can be completed in the presence of only two proteins, the RdRp and the CP.

The members of the genus *Betachrysovirus*, a very recent addition to the family *Chrysoviridae*, are not as well characterized. They typically have four or five genomic segments and, in the case of CfCV1, up to seven segments. The RdRp, the CPs, and betachryso-P3 and betachryso-P4 are conserved among all betachrysoviruses, while the rest, if present, are non-homologous among members of the genus. The RdRp of the betachrysoviruses is most closely related to that of their sister taxon *Alphachrysovirus*, but the proteins encoded from the other segments, including the CP, demonstrate no clear homology with those of the alphachrysoviruses or other proteins available in the databases.

Biology and Effects of Chrysoviruses on Fungal Hosts

Mycoviruses may reduce or increase the virulence of their fungal hosts and as such are considered to have potential as biological control agents. *Cryphonectria hypovirus 1* (CHV1), a positive-sense single-stranded RNA mycovirus belonging to the family *Hypoviridae*, is the best example for attenuation of the host fungus of *Cryphonectria parasitica*. Viruses belonging to the family *Chrysoviridae* have also been reported to alter the pathogenicity of their host fungi. Within the genus *Alphachrysovirus*, AfuCV reduces growth and pathogenicity of its human pathogenic host. Additionally, five mycoviruses which belong to genus *Betachrysovirus*, have been reported

to alter the pathogenicity of their host fungi against plants including MoCV1-A, AaCV1, BdCV1, *Fusarium graminearum* mycovirus-China 9 (FgV-Ch-9) and *Aspergillus thermomutatus* chrysovirus 1 (AthCV1). For instance, MoCV1-A infection generally confers hypovirulence to the fungus but is also a driving force to generate different pathogenic races of the fungus. In another example, AaCV1 exhibits two contrasting effects: it impairs the growth of the host fungus while rendering the fungus hypervirulent to the plant, with increased production of a host-specific toxin.

MoCV1-A and MoCV1-B are the first viruses reported to cause hypovirulence traits in the rice blast pathogen *Magnaporthe oryzae*, including impaired growth of host cells, altered colony morphology, and reduced pigmentation. The hyphal morphology of the host fungus infected with MoCV1-B revealed a remarkable albino phenotype on potato dextrose agar (PDA) medium, indicating that melanin biosynthesis appears to be suppressed by MoCV1-B infection. The cell wall of a MoCV1-B infected strain was loose and enlarged, and staining with calcofluor-white showed that the cell wall was also damaged by MoCV1-B infection. No conidial formation was observed *M. oryzae* infected with MoCV1-B on PDA. Pathogenic races of *M. oryzae* are determined by a gene-for-gene system, where an avirulence gene in the pathogen induces disease resistance in a rice variety with a corresponding resistance (R) gene. To examine whether MoCV1-A infection affects pathogenic races of *M. oryzae*, a virus-free and a MoCV1-A-infected *M. oryzae* strain were inoculated onto different rice varieties. Inoculation of the R gene-free rice variety showed that MoCV1-A infection resulted in reduced fungal virulence. However, when spray or leaf-sheath inoculation methods were used to inoculate monogenic rice lines carrying different R genes MoCV1-A-infected and MoCV1-A-free *M. oryzae* strains caused different lesion types (resistance to susceptible or *vice versa*) on individual rice varieties. These data suggest that MoCV1-A infection can alter the pathogenicity of the host *M. oryzae* from avirulence to virulence, or from virulence to avirulence, depending on the rice variety.

Recently, it has been found that infection of the Japanese pear pathotype fungus, *Alternaria alternata* with AaCV1 simultaneously impaired growth of the host fungus and increased levels of the host-specific AK-toxin. This is another example of a mycovirus infection causing changes in pathogenic races of the host fungus, because *A. alternata* can infect some specific varieties of Japanese pear (*Pyrus pyrifolia* Nakai) cultivar Nijisseiki, but not others. It is likely that the enhancement of host fungal pathogenicity in some varieties, without any mutation in the avirulence genes, is one of the strategies used by mycoviruses to survive in the agricultural ecosystem, where humans cultivate many plant varieties with different R genes to reduce damage caused by plant disease. Mycoviruses may increase survival rates by retaining the diversity of avirulence genes in their host fungi, which are important for fungal adaptation to plants. Since only limited sequence information is currently available for betachrysovirus dsRNA genomes it is difficult to assign potential roles for individual dsRNA encoded products in plant pathogenicity. Recently attempts at dissecting the roles of the five MoCV1-A dsRNA encoded proteins in pathogenicity have been reported using over expressed proteins. The putative protein encoded by MoCV1-A dsRNA1 contains eight conserved motifs characteristic of RdRps and is assumed to function in this role. However, based on BLAST searches, it was not possible to predict the functions of the other four putative proteins. Therefore, shuttle vectors were constructed by ligating each of the remaining four MoCV1-A ORF sequences predicted from the genomic sequences of dsRNAs 2–5 downstream of a low expression promoter (*ADH1*) or a high expression promoter (*TDH3*) for expression in yeast cells. The influence of each protein on yeast cell growth was investigated in liquid cultures. Optical density, viable cell number, glucose concentration, and pH were measured together with observations of cell morphology and immunological analyses. Abnormalities in cell morphology including the appearance of enlarged vacuoles and vesicles were observed when the CP (encoded by dsRNA 4; [Table 1](#)) was over expressed in yeast cells. A series of cultivation tests revealed that CP expression also caused a decrease in the rate of cell proliferation and a decrease in cell life span. Over expression of the CP in the human pathogenic budding yeast *Cryptococcus neoformans* also caused a decrease in the growth rate, increase in emergence and enlargement of vacuoles. Additionally, the formation of capsules, which are involved in the pathogenicity of *C. neoformans*, was also reduced in the CP-expressing cells, suggesting a reduction in pathogenic potential. Expression of a CP-GFP fusion protein in *S. cerevisiae* resulted in the formation of abnormal cell aggregates. In MoCV1-A, CP expression also resulted in significant inhibition of growth at high temperatures (35°C and 37°C) as compared to cells grown at the optimal temperature (30°C) plus reduced expression of stress-response genes and increased expression of translation-related genes. The MoCV1-A CP showed significant similarity to related proteins from other viruses in genus *Betachrysovirus*. Multiple alignments of the CP-related protein sequences showed that their central regions (aa 210–591 in MoCV1-A CP) are relatively conserved. Indeed, yeast transformants expressing the conserved central region of the MoCV1-A CP protein (325–575 aa) showed similar impaired growth phenotypes to those observed in yeast expressing the full-length MoCV1-A CP protein. The yeast heterologous expression system revealed that the CP proteins of MoCV1-A and AaCV1 (in this case encoded by dsRNA 2) were responsible for growth inhibition of the yeasts *S. cerevisiae* and *C. neoformans*, suggesting that the CP in addition to its structural role may have been preserved in betachrysoviruses as a protein implicated in hypovirulence. This hypothesis is supported by a recent report showing that the structural protein of another betachrysovirus, FgV-Ch-9 (closely related to FgV2), acts as symptom determinant.

Acknowledgment

This work is dedicated to the memory of our friend and colleague Said Ghabrial, who sequenced the first chrysovirus in 2000 and passed away in November 2018.

This is an update of S. Tavantzis, Partitiviruses of Fungi, In Encyclopedia of Virology (Third Edition), edited by Brian W.J. Mahy and Marc H.V. Van Regenmortel, Elsevier Ltd., 2008, doi:10.1016/B978-012374410-4.00405-2.

Glossary

Ascomycete/basidiomycete Ascomycetes (phylum Ascomycota) are fungi that produce sexual spores inside sac-like structures called asci, whereas basidiomycetes (phylum Basidiomycota) produce sexual spores externally on specialized cells called basidia.

Capsid Protective shell composed of multiple copies of protein subunits that encapsidate the viral genome.

Heterokaryotic/homokaryotic Nuclear condition of hyphal cells among many basidiomycetes. The germination of a single basidiospore results in the formation of a homokaryotic (i.e., multinucleate but effectively haploid) primary mycelium. A compatible mating between two homokaryotic mycelia produces a heterokaryotic (i.e., multinucleate but effectively diploid) secondary mycelium with two different nuclear haplotypes. Two different heterokaryons are somatically incompatible unless

they are very closely related. In ascomycetes, the vegetative mycelium is usually haploid and uninucleate.

Hyphal anastomosis Fusion of hyphal cells allowing cytoplasmic exchange between contacting mycelia.

Hypovirulence Reduced ability to cause disease. Often associated with the presence of mycoviruses in plant pathogenic fungi.

Icosahedral symmetry Arrangement of the capsid protein subunits of isometric (spherical) viruses in the symmetry of an icosahedron consisting of 60 identical objects or asymmetric units. In the so called “ $T = 2$ ” symmetry, 120 identical protein monomers form 60 asymmetric dimers.

Somatic incompatibility Process of allorecognition in fungi that keeps different fungal genotypes separated. Somatic (vegetative) incompatibility leads to programmed cell death of heterokaryotic cells formed after anastomosis between hyphae of genetically incompatible strains.

Introduction

Viruses infecting fungi (mycoviruses) were first discovered by M. Hollings in diseased strains of the commercially cultivated mushroom, *Agaricus bisporus* in the 1960s. Later during the same decade, the first members of current virus family *Partitiviridae* were found in isolates of the ascomycetous mold fungus *Penicillium* spp. Mycoviruses are now known to be very common among fungi. They are found in diverse fungal phyla including ascomycetes, basidiomycetes, chytridiomycetes and zygomycetes with various lifestyles ranging from symbionts to pathogens. The following classified virus families include viruses infecting fungi: *Alphaflexiviridae*, *Barnaviridae*, *Botourmiaviridae*, *Deltaflexiviridae*, *Endornaviridae*, *Gammapartitiviridae*, *Hypoviridae* and *Narnaviridae* with positive-sense single-stranded (ss) RNA genomes; *Myonnaviridae* with negative-sense ssRNA genomes; *Amalgaviridae*, *Chrysovriidae*, *Megabirnaviridae*, *Partitiviridae*, *Reoviridae*, *Totiviridae* and *Quadriviridae* with double-stranded (ds) RNA genomes; and *Genomoviridae* with ssDNA genomes. In addition, the classified genus *Botybirnavirus* includes dsRNA viruses found so far only in fungi. Virus families *Metaviridae* and *Pseudoviridae* contain retrotransposable elements found in ascomycetous yeast fungi, plants, insects and nematodes.

Viruses belonging to the family *Partitiviridae* are classified into five different genera with characteristic hosts for members of each genus: either plants or fungi for genera *Alphapartitivirus* and *Betapartitivirus*; fungi for genus *Gammapartitivirus*, plants for genus *Deltapartitivirus* and protozoa for genus *Cryspovirus*. The name “partitivirus” originates from the Latin word “*partitius*”, which means “divided” and refers to the genome structure of these viruses, which is bipartite and consists of two linear monocistronic dsRNAs. The term “cryptovirus” (from Greek “*crypto*,” meaning “hidden, covered, or secret”) was formerly used in genus names of plant-infecting *Partitiviridae* members, but since many of the fungal partitiviruses can also be considered cryptic (symptomless), this term is no longer used to differentiate between plant and fungal partitiviruses. Plant and protozoal partitiviruses are discussed in detail elsewhere in this encyclopedia.

Classification

This article focuses on the genera *Alphapartitivirus*, *Betapartitivirus*, and *Gammapartitivirus*, which include viruses that infect filamentous fungi. In addition to characteristic hosts ranges within each genus, partitivirus genera are demarcated based on genome segment and protein lengths within a typical size range for each genus, separate phylogenetic grouping of RdRP sequences from each genus, and level of amino acid sequence identity (less than 24% in pairwise comparisons of viruses from different genera).

There are currently 28 fungal partitiviruses that have been assigned to a genus: ten alphapartitiviruses, ten betapartitiviruses, and eight gammapartitiviruses. In addition, the genomes of several more partitiviruses have been completely sequenced and

described in scientific publications. The classified species of the family *Partitiviridae* found in fungi are listed in [Table 1](#), and tentative new *Partitiviridae* members with complete published genome sequences are shown in [Table 2](#). Sequence information is lacking from the classified partitiviruses *Agaricus bisporus virus 4*, and *Gaeumannomyces graminis* viruses 019/6-A and T1-A, and they remain unassigned to a genus.

Virion Structure

Partitivirus particles are isometric, non-enveloped, and 25–43 nm in diameter ([Fig. 1](#)). The capsid consists of 120 copies of a single capsid protein (CP) arranged as 60 dimers with T=1 icosahedral symmetry. Dimeric “arch-like” surface protrusions are frequently observed on partitivirus capsids. Virion buoyant densities in CsCl gradients range from 1.34 to 1.44 g cm⁻³ for particles with nucleic acid.

The structures of four fungal partitiviruses have been determined by electron cryomicroscopy and 3D reconstruction ([Fig. 2](#)). These include the gammapartitiviruses *Penicillium stoloniferum virus F* and *S* (PsV-F and PsV-S), and the betapartitiviruses *Fusarium poae virus 1* (FpV1) and *Sclerotinia sclerotiorum partitivirus 1* (SsPV1). The structure of PsV-F has also been resolved with X-ray crystallography.

Partitiviruses possess two essential genome segments that are individually encapsidated in separate particles. Virion-associated RNA polymerase activity is present, and one or two molecules of RNA dependent RNA polymerase (RdRP) are packaged inside each particle. Purified virion preparations contain mature virions and a heterogenous population of particles thought to be replicative intermediates that may contain only one ssRNA molecule (the genomic positive strand), or both ssRNA and dsRNA, or two molecules of dsRNA.

Genome

The two essential genome segments of partitiviruses are separately encapsidated, and each linear segment contains one large ORF on the positive strand RNA molecule. One segment/ORF (dsRNA1) encodes the RdRP, whereas the other segment/ORF (dsRNA2) encodes the capsid protein (CP) ([Fig. 3](#)). The CP encoding genome segment is usually smaller than the polymerase encoding

Table 2 List of tentative fungal partitiviruses with complete genome sequences. Putative affiliation with the classified genera *Alpha-* *Beta-* and *Gammapartitivirus* is indicated using the corresponding Greek alphabets. The two essential genome segments are named as dsRNA1 and dsRNA2

segment. The total size of partitivirus genomes is typically 3.6–3.9 kbp for members of genus *Alphapartitivirus*, 4.3–4.8 kbp for members of genus *Betapartitivirus*, and 3.1–3.4 kbp for members of genus *Gammapartitivirus*. The genome segments are individually 1.4–2.4 kbp in size. **Table 3** shows the size ranges of individual genome segments in classified alpha- beta- and gammapartitiruses, as well as the predicted sizes of RdRP and capsid proteins.

The first 7–20 nucleotides in the 5′–non translated region of the coding RNA are usually highly conserved between the two genome segments of single viruses and may form stem-loop structures. Such conserved terminal sequences are believed to be involved in polymerase recognition for replication and/or RNA packaging. Members of genera *Alphapartitivirus* and *Betapartitivirus* typically possess poly(A) tracts which may be interrupted by other nucleotides near the coding-strand 3′ terminus of one or both genome segments, whereas gammapartitiruses usually lack terminal poly(A) tracts.

Besides the two essential genome segments, some partitiviruses have additional (satellite or defective) dsRNA elements. Apparent RNA satellites encoding small (237–303 aa) proteins, homologous to each other but not to either CP or RdRP, are present in several classified and tentative gammapartitiruses, including *Aspergillus ochraceus* virus, *Discula destructiva* virus 1, *Gremmeniella abietina* RNA virus MS1, and *Ustilaginoidea virens* partitivirus 1 (**Tables 1** and **2**). RNA satellites appearing not to encode any proteins are found associated with studied isolates of the alphapartitivirus Cherry chlorotic rusty spot associated partitivirus, the betapartitivirus *Atkinsonella hypoxylon* virus, and gammapartitiruses *Discula destructiva* virus 1 and *Penicillium stoloniferum* virus F (**Tables 1** and **2**). The third genome segment of alphapartitivirus *Rosellinia necatrix* partitivirus 2 (**Table 1**) is a truncated version of the RdRP that may function as defective-interfering RNA.

Life Cycle

The model for partitivirus replication has been inferred based on in vitro studies of virion-associated RdRP of the gammapartitivirus *Penicillium stoloniferum* virus S, and isolation of particles that represent various stages in the replication cycle from naturally infected mycelium (**Fig. 4**). The virion-associated RdRP mediates positive-strand RNA synthesis within the virus particle

Fig. 1 Electron micrographs of *Penicillium stoloniferum* virus S. Samples were negatively stained in 2% uranyl acetate (a) or prepared unstained and vitrified (b). Micrographs were recorded on a CCD detector in an FEI Polara transmission electron microscope operated at 200 keV with samples at (a) room or (b) liquid nitrogen temperatures. In (a) bacteriophage P22 (five largest particles) was mixed with PsV-S to serve as a calibration reference. Heavy metal stain surrounds virions (e.g., black arrow) and contrasts their surfaces against the background carbon support film. Stain penetrates into the interior of 'empty' capsids (e.g., white arrow), resulting in particle images in which only a thin, annular shell of stain-excluding material (capsid) is seen. In (b) the unstained PsV-S sample was vitrified in liquid ethane. Here particles appear dark (higher density) against a lighter background of surrounding water (lower density). The inset shows a three-times enlarged view of an individual particle, in which several knobby surface features are clearly visible. Reproduced from Ghabrial, S.A, Ochoa, W.F, Baker, T.S, Nibert, M.L., 2008. Partitiviruses: General features. In: Mahy, B.W.J., van Regenmortel, M.H.V (Eds.), *Encyclopedia of Virology*, third ed. Oxford: Elsevier, pp. 68–75. with permission from Elsevier.

Fig. 2 Three-dimensional (3D) structure of PsV-S. (a) Shaded, surface representation of PsV-S 3D reconstruction viewed along an icosahedral twofold axes. The 3D map is color-coded to emphasize the radial extent of different features (yellows and greens highlight features closest to the particle center, and oranges and reds those farthest from the center). A total of 60 prominent protrusions extend radially outward from the capsid surface. Each protrusion exhibits an approximate dyad symmetry, which is consistent with the expectation that the partitivirus capsid consists of 120 capsid protein monomers, organized as 60 asymmetric dimers in a so-called 'T=2' lattice. (b) Density projection image of a central, planar section through the PsV-S 3D reconstruction (from region marked by dashed box in (a)). Darker shades of gray correspond to higher electron densities in the map section and lighter shades represent low-density features such as water outside as well as inside the particles. The capsid shell appears darkest because it contains a closely packed, highly ordered (icosahedral) arrangement of capsid subunits. The genomic dsRNA on the inside appears at lower density, in part because the RNA is not as densely packed and in part because the RNA adopts a less ordered arrangement. The protrusions seen in (a) appear as large 'bumps' in the central section view that decorate the outside of a contiguous, ~2 nm thick, shell. Arrows point to faint density features that appear to form contacts between the inner surface of the protein capsid and the underlying RNA. These contacts occur close to the fivefold axes of the icosahedral shell. Reproduced from Ghabrial, S.A, Ochoa, W.F., Baker, T.S., Nibert, M.L., 2008. Partitiviruses: General features. In: Mahy, B.W.J., van Regenmortel, M.H.V. (Eds.), *Encyclopedia of Virology*, third ed. Oxford: Elsevier, pp. 68–75. with permission from Elsevier.

Fig. 3 Atkinsonella hypoxylon virus (AhV), an isolate of the type species of the genus *Betapartitivirus*, has a bipartite genome consisting of dsRNA1 and dsRNA2. dsRNA1 contains the RdRp ORF (nt positions 40–2038) and dsRNA2 codes for the CP ORF (nt positions of 72–2030). The RdRp and CP ORFs are represented by rectangular boxes. Reproduced from Ghabrial, S.A., Buck, K.W., Hillman, B.I., Milne, R.G., 2005. *Partitiviridae*. (Eds.), *Virus Taxonomy: Eighth Report of the International Committee on Taxonomy of Viruses*, San Diego, CA: Elsevier Academic Press, pp. 581–590. with permission from Elsevier.

Table 3 Size ranges of individual genome segments in classified members of genera *Alpha-* *Beta-* and *Gammapartitivirus*, and the predicted sizes of their RdRP and capsid proteins

Genus	dsRNA1 (bp)	dsRNA2 (bp)	RdRP		CP	
			aa	Mr (kDA)	aa	Mr (kDA)
<i>Alphapartitivirus</i>	1873–2027	1708–1866	581–621	68–73	463–521	51–57
<i>Betapartitivirus</i>	2180–2444	2135–2354	663–746	77–87	636–686	71–77
<i>Gammapartitivirus</i>	1645–1787	1445–1611	519–539	60–62	413–443	44–47

using the negative strand of the genome dsRNA as a template by a semi-conservative mechanism. The newly synthesized positive-strand RNA is retained inside the particle as part of the dsRNA while the parental genomic positive strand (encoding RdRP or CP) is released from the particle and used in translation or in packaging into a new partitivirus particle. The monocistronic positive-sense transcripts of both genomic dsRNAs are translated by cellular ribosomes and virions accumulate in the cytoplasm. The replicase activity of the RdRP is believed to catalyze the synthesis of negative-strand RNA on the positive-strand template within the assembling virion, thereby reconstituting a genomic dsRNA segment.

Epidemiology

Fungal partitiviruses are transmitted intracellularly during cell division, hyphal anastomosis (i.e., cell fusion between fungal strains), and sporogenesis. Vertical virus transmission may occur by sexual spores (basidiospores or rarely ascospores) derived from virus-infected fruiting bodies as well as vegetative spores (conidia). In ascomycetous fungi, such as *Penicillium stoloniferum*, *Gremmeniella abietina*, and *Ustilaginoidea virens*, transmission of partitiviruses through asexual spores is highly efficient, and 90%–100% of single conidia receive these viruses. Only part of basidiomycetous fungi produce asexual spores, and the proportion of virus-infected conidia seems to vary even among isolates of the same host species. In different isolates of the basidiomycete *Heterobasidion parviporum*, two different unclassified alphapartitiviruses were found to be transmitted to 3%–55% of germinated conidia. The basidiospores of this fungus also carry dsRNA elements consistent with partitiviruses, which have been detected in 10%–84% of basidiospores derived from virus-infected fruiting bodies. In many ascomycetes (e.g., *Gaeumannomyces graminis*, *Rosellinia necatrix*, and *Gremmeniella abietina*), partitiviruses are usually eliminated during ascospore formation.

There are no known natural vectors for partitiviruses. Therefore, the horizontal transmission of fungal partitiviruses is regulated by host systems governing hyphal fusion, i.e., somatic (vegetative) incompatibility, mating type incompatibility and intersterility. Inoculation experiments in field conditions have revealed that the unclassified alphapartitivirus *Heterobasidion partitivirus* 4 (HetPV4) (GenBank HQ541325; JX271788-9) is transmitted between conspecific host isolates by two different means: (1) mating between an introduced heterokaryotic virus donor strain and a resident homokaryotic *Heterobasidion* strain, and (2) mycelial contact between two somatically incompatible heterokaryons. In *Rosellinia necatrix*, the transmission of partitiviruses between somatically incompatible isolates of the host fungus can be enhanced by the addition of zinc ions, which promotes hyphal fusion and retards the cell death reaction during an incompatible anastomosis. On the other hand, horizontal transmission of *Rosellinia necatrix* partitivirus 1 (RnPV1) is hindered by the presence of a mycoreovirus, MyRV3, of *Rosellinia necatrix* in the recipient fungal colony. Therefore, pre-existing viral infections may affect the transmissibility of partitiviruses between host isolates.

Partitiviruses are occasionally transmitted across species borders in both laboratory and field conditions. Dual fungal cultures have been used for the transmission of *Heterobasidion* partitiviruses between congeneric host species. Microscopic examination has revealed occasional anastomosing cells between two intersterile *Heterobasidion* species, *H. ecrustosum* and *H. abietinum*, which resulted in subsequent death of the cells involved, but allowed for between-species transmission of the alphapartitivirus HetPV3

Fig. 4 Model for the replication strategy of *Penicillium stoloniferum* virus S. The open circles represent capsid protein (CP) subunits and the closed circles represent RNA-dependent RNA polymerase (RdRP) subunits. Solid lines represent parental RNA strands whereas wavy lines represent newly synthesized progeny RNA strands. Virion preparations include mature virions with either dsRNA1 or dsRNA2, but also a small proportion of particles that contain only one ssRNA molecule corresponding to the genomic positive strand of the respective dsRNAs, and a heterogeneous population of particles more dense than the mature virions. These heavy particles are believed to represent different stages in the replication cycle, including particles containing the individual genomic dsRNAs with ssRNA tails of varying lengths, particles with one molecule of dsRNA and one molecule of its ssRNA transcript, and particles containing two molecules of dsRNA. Reproduced from Ghabrial, S.A., Hillman, B.I., 1999. Partitiviruses-fungal (*Partitiviridae*). In: Granoff, A., Webster, R.G. (Eds.), Encyclopedia of Virology, second ed. San Diego: Academic Press, pp. 1477–1151. with permission from Elsevier.

(Table 1). Partitiviruses have also been introduced to more distantly related host species by transfecting fungal protoplasts with purified virions. This has been accomplished in *C. parasitica* using partitiviruses of *Rosellinia necatrix* (RnPV1 and RnPV2; Tables 1 and 2), and in *Botrytis cinerea* with SsPV1. In addition, protoplast transfection has been used to transmit viruses between con-specific strains in *B. cinerea* and *Aspergillus fumigatus*.

Sequence analysis has revealed nearly identical alphapartitivirus strains (HetPV11-au1 and HetPV11-pa1; GenBank HQ541328–9 and MG948857–8) in two intersterile species of *Heterobasidion* (*H. australe* and *H. parviporum*) within the same region in Bhutan, suggesting natural transmission of HetPV11 between these fungal species. Conspecific betapartitiviruses have also been described in the ascomycetous blue-stain fungi *Ceratocystis resinifera* (Table 1) and *C. polonica* (GenBank AY247204–5). Similar partitiviruses sharing over 90% RdRp aa sequence identity (the threshold for species demarcation in the family *Partitiviridae*) are sometimes found in divergent host species. For example, gammapartitiviruses found in the ascomycetes *Colletotrichum truncatum* (a plant pathogen) and *Sodiomyces alkalinus* (an alkalophile) seem to be conspecific (GenBank KR074421 and KY484539–40), and alphapartitiviruses infecting the basidiomycete fungi *Heterobasidion parviporum* (order Russulales) and *Megacollybia platyphylla* (order Agaricales) are likewise closely related (JN606085; KI733076).

The genera *Alphapartitivirus* and *Betapartitivirus* include viruses isolated from both fungi and plants. Therefore, a capacity for occasional successful transmission of these viruses between fungal and plant hosts appears likely. Some of the viruses in these genera are found in plant pathogenic fungi, which suggests a potential route for horizontal transmission between fungi and plants. Notably, highly similar partitiviruses have been detected in sugar beet (*Beta vulgaris*) and a basidiomycete fungus infecting its leaves, *Helicobasidium purpureum*. Thus, the partial polymerase sequence of *Helicobasidium purpureum* partitivirus (GenBank AY949837) is 99% identical to that reported for Beet cryptic virus 1, suggesting that the virus may have been transmitted between the associated organisms. This view is further supported by an in vitro transfection study showing that *Penicillium aurantiogriseum* partitivirus 1 (GenBank KT601103–4) is capable of replicating in the *Nicotiana tabacum* BY2 cell line.

Pathogenesis

Partitiviruses are found in all parts of an infected mycelium and can accumulate to very high concentrations (at least 1 mg of virions per one gram of mycelial tissue for *Penicillium stoloniferum* virus F). The transmission of betapartitivirus RnPV1 within

and between *R. necatrix* colonies has been visualized by a colony-print immunoassay, which revealed that the virus was distributed throughout host colonies. However, growing hyphal tips may remain virus-free for a period of time, and then single hyphal tip isolation can be used for curing fungal isolates of partitiviruses. In nature, clonally spreading mycelia of long-living root rot pathogens (such as *Heterobasidion* spp. and *Helicobasidium mompa*) typically consist of virus-infected and virus-free hyphal sections.

Mixed infections of fungal hosts with two or more different partitiviruses have been observed in several species. The gammamapartitiviruses PsV-S and PsV-F were originally found in a single isolate of *Penicillium stoloniferum*. Stable partitivirus co-infections are also found in strains of *Heterobasidion* spp. that may host two different alphapartitiviruses (HetPV16 and HetPV20; GenBank KY859977 and MG566085–6) or alpha- and betapartitiviruses (HetPV9 and HetPV7; GenBank JN606085 and JN606090–1). Co-infections by alpha- and betapartitiviruses occur also in *Helicobasidium mompa* (GenBank AB110979 and AB110980), and mixed infections by two different alphapartitiviruses are found in *Rhizoctonia solani* (KX914900–3). The most striking example of mixed partitivirus infections has been described in single isolates of mycorrhizal *Ceratobasidium* fungi that may host at least five and up to ten different alpha- and betapartitiviruses (GenBank KU291902–22). These fungi occur as root symbionts of *Pterostylis sanguinea* orchids in Australia.

Mixed infections of fungal isolates with partitiviruses and unrelated viruses are also relatively common. The *Rosellinia necatrix* strain hosting RnPV1 is naturally co-infected with *Rosellinia necatrix* megabirnavirus 2 (RnMBV2), and a single strain of the conifer pathogen *Gremmeniella abietina* has been shown to harbor three unrelated viruses (the gammapartitivirus *Gremmeniella abietina* RNA virus MS2, a mitovirus and a totivirus). Similarly, partitiviruses infecting strains of *Heterobasidion* spp. may co-occur with mitoviruses or isolates of the unclassified species *Heterobasidion* RNA virus 6, and *Botryosphaeria dothidea* partitivirus 1 (GenBank KF688740–1) occurs in a mixed infection with a chrysovirus. A mixed infection by a betapartitivirus (GenBank KY296404–5), gammapartitivirus (KY484539–40), and a fusarivirus was described in an isolate of *Sodiomyces alkalinus*.

In general, fungal partitiviruses seem to be associated with symptomless infections of their hosts. However, some of them have deleterious effects on host cells. The unclassified alphapartitivirus *Rhizoctonia solani* partitivirus 2 (Table 2) causes hypovirulence in *Rhizoctonia solani*, a soil-borne basidiomycete fungus. Similarly, the unclassified betapartitivirus SsPV1 (Table 2) has been shown to reduce the virulence of its natural host as well as *Botrytis cinerea* after protoplast transfection. Moreover, *Aspergillus fumigatus* partitivirus 1 (Table 2) seems to mediate reduced growth rate, conidiation and pigmentation in *Aspergillus fumigatus*, and the alphapartitivirus HetPV13-an1 (Table 1) causes drastic growth reduction in several strains of *Heterobasidion annosum* and *H. parviporum*. In contrast, the gammapartitivirus *Talaromyces marneffe* partitivirus 1 (Table 2) seems to enhance the virulence of its native host, which causes opportunistic infections in mammals, including immunosuppressed humans. In some cases, host symptoms may only develop during viral co-infection: a mixed infection by RnPV1 and RnMBV2 leads to host hypovirulence, while the individual viruses exhibit asymptomatic infections.

Taxonomic and Phylogenetic Considerations

Phylogenetic analyses of the predicted amino acid sequences of partitivirus RdRPs show that the classified fungal partitiviruses are included in three distinct clusters corresponding to the genera *Alphapartitivirus*, *Betapartitivirus*, and *Gammapartitivirus* (Fig. 5). However, certain unclassified partitiviruses seem to form a lineage distinct from established partitivirus genera. Based on sequence identity scores and phylogenetic analysis, this virus clade includes *Botryosphaeria dothidea* partitivirus 1, *Alternaria alternata* partitivirus 1 and *Aspergillus fumigatus* partitivirus 2 (Table 2), which are only distantly related to members of genus *Gammapartitivirus* (Fig. 5).

The discovery of a gammapartitivirus in the oomycete *Pythium nunn* in 2018 (GenBank accession LC371062 and LC371063; Fig. 5) expands the host range of partitiviruses to the phylum Stramenopila, which is evolutionarily distinct from fungi and includes organisms with flagellated zoospores ranging from plant pathogenic oomycetes to macroscopic brown algae. It should also be noted that virus sequences resembling known partitiviruses have been discovered in various insect species with high throughput sequencing. Whether these viruses are hosted by the insects or associated microbes remains to be investigated. The putative RdRP of the unclassified *Penicillium aurantiogriseum* partiti-like virus (GenBank accession KT601105) seems to be related to these insect-derived partiti-like sequences, but its taxonomical status remains to be determined, and it seems to form a lineage separate from the classified partitivirus genera.

The evolutionary rate of partitivirus CPs is considerably higher than that of the RdRPs, and pairwise amino acid sequence identities between members of different partitivirus genera are typically less than 10%. Therefore, phylogenetic analyses based on the CP sequences show weaker statistical support than analysis of RdRP sequences. Dendrograms separately constructed from either RdRP or CP sequences seem to reveal essentially the same grouping, but are not entirely congruent. In some cases, the RdRP and CP sequences of a single virus strain show slightly different phylogenetic grouping, suggesting that segment reassortment may occasionally occur among congeneric virus strains in the family *Partitiviridae*. The *Heterobasidion* betapartitivirus HetPV8 and alphapartitivirus HetPV20 (Tables 1 and 2) are examples of such cases.

Based on genome organization and sequence similarity, members of the family *Partitiviridae* are related to a separate and currently unclassified group of fungal dsRNA viruses with two small genome segments (each 1.7–2.4 kbp). These include the mutualistic *Curvularia* thermal tolerance virus, at least five other viruses with published genome sequences (Table 4), and several isolates with unpublished and/or incomplete genome sequences from the fungal genera *Cryphonectria*, *Gremmeniella*, *Lactarius*, *Myriodontium*, *Rhizoctonia*, *Sclerotium*, and *Trichoderma*. The larger genome segment of these viruses has a single ORF encoding an

Fig. 5 Unrooted Maximum Likelihood dendrogram constructed based on the complete deduced amino acid sequences of RdRPs of approved members of the family *Partitiviridae* and selected unclassified partitiviruses. The sequences were aligned using MAFFT v7.388 in Geneious R10 (Biomatters Ltd.) and the evolutionary history was inferred using MEGA 7. The percentage of replicate trees in which the associated taxa clustered together in the bootstrap test (100 replicates) are shown next to the branches. The evolutionary distances were computed using the Le Gascuel 2008 model (LG + G + I) and are in the units of the number of amino acid substitutions per site. Virus names and GenBank accession numbers corresponding to RdRP nucleotide sequences are given.

Table 4 Exemplar isolates of unclassified viruses forming a separate phylogenetic clade related to members of virus family *Partitiviridae*, including the mutualistic *Curvularia* thermal tolerance virus

<i>Virus isolate</i>	<i>GenBank accession</i>	
	<i>dsRNA1</i>	<i>dsRNA2</i>
<i>Curvularia</i> Thermal Tolerance Virus	EF120984	EF120985
<i>Penicillium aurantiogriseum</i> bipartite virus 1	KT601101	KT601102
<i>Fusarium graminearum</i> dsRNA mycovirus 4	GQ140627	GQ140628
<i>Rhizoctonia solani</i> dsRNA virus 1	JX976612	JX976613
<i>Sclerotium hydrophilum</i> virus 1	KU886558	KU886559
<i>Heterobasidion</i> RNA virus 6	HQ189459	MK468678

RdRP of 592–692 aa, whereas the smaller segment has 1–2 ORFs of unknown function. Members of a recently described group of viruses provisionally designated as “Unirnaviruses” also share moderate levels of RdRP homology with partitiviruses, but their genomes are nonsegmented. Viruses with quadripartite genomes currently classified in the family *Chrysoviridae* were formerly included in the family *Partitiviridae*, but a separate family was formed in 2002 to accommodate these viruses as described elsewhere in this encyclopedia.

Members of the family *Megabirnaviridae* and genus *Botybirnavirus* have bisegmented genomes and infect fungi, but their genomes are substantially larger than those of partitiviruses (8.9 kbp and 7.2 kbp for the exemplar strain RnMBV1; 6.2 kbp and 5.9 kbp for *Botrytis porri* RNA virus 1, the only classified member of the genus *Botybirnavirus*). The larger genome segment of megabirnaviruses and botybirnaviruses encodes a CP and RdRP. These virus families are discussed in detail elsewhere in this encyclopedia. Finally, members of the family *Partitiviridae* have properties similar to members of the family *Picobirnaviridae*, e.g., the genomes are bisegmented, and the capsids are small (<45 nm in diameter) with 120 subunits organized as 60 dimers in “T=2” symmetry. The picobirnaviruses, however, are phylogenetically distinct and probably have other basic differences including co-packaging of both genome segments and capacity for extracellular transmission. Picobirnaviruses are found in vertebrates rather than plants, fungi and protozoa.

Fusariviruses (Unassigned)

Sotaro Chiba, Nagoya University, Nagoya, Japan

© 2021 Elsevier Ltd. All rights reserved.

Glossary

Hypovirulence The reduced pathogenicity of fungal pathogens, in terms of abilities to infect, grow, colonize, and destruct the host organisms, and is generally associated with mycovirus infections.

Sub-genomic RNA An RNA segment shorter than the full-length genome of an RNA virus that expresses protein encoded by downstream ORFs.

Introduction

Mycoviruses (fungal viruses) are increasingly reported with an aid of improved sequencing technology and this has uncovered the highly diverse nature of mycoviruses. Consequently, in the past decade, several new fungal viral taxa, such as the families *Megabirnaviridae*, *Quadriviridae*, and *Mymonaviridae*, have been established. Many reported viruses have still not been assigned to existing viral taxa, even though it has been a long time since the initial discovery and characterization of some of these viruses. One good example is the *Fusarium graminearum* virus 1 strain DK21 (FgV1-DK21), which was identified in Korea in 2002 and thoroughly characterized in 2007. This virus is still taxonomically floating and had been recorded as an unassigned or unclassified virus in the 9th and 10th editions of the International Committee on Taxonomy of Viruses (ICTV) report, published in 2011 and 2018–2019. The related article in the current edition of ICTV report can also be accessed online (see “Relevant Website section”).

Since 2014, viruses that are evolutionarily associated with FgV1-DK21 have been continuously reported, although the genomic structures of those viruses are not identical to that of FgV1-DK21. Therefore, the need for grouping these viruses becomes obvious today. With this in mind, Japanese researchers previously proposed the provisional new genus, *Fusarivirus*, in the new family, *Fusariviridae*, in 2014. The proposed genus/family name was created after the host name of FgV1-DK21, *Fusarium graminearum* (reclassified as *F. boothii*), and thereafter, the terms became widely used to classify the potential members of the group. However, as of 2019, the creation of this new taxon is still incomplete. In this article, the known information on fusariviruses reported so far is briefly summarized, with a view to establish the *Fusarivirus* genus under the family *Fusariviridae*. The future direction of research on fusariviruses is also discussed below.

Taxonomy and Classification

Potential members of the provisional genus *Fusarivirus* are listed in [Table 1](#). From this point onwards, viruses that are members of this genus are described as fusariviruses. The representative species in the provisional genus is *Fusarium graminearum* virus 1, which was first discovered in 2002. A phylogenetic analysis based on the amino acid sequences of the RNA dependent RNA polymerase (RdRp) domain in replication-associated proteins (motifs 1–8) resulted in two major clades: group I, which accommodates FgV1-DK21 and typical fusariviruses with two clearly separated subgroups in the clade, and groups II and III, which are in the same clade that is formed independently of group I (groups II and III are differentiated by their genomic structures) ([Fig. 1](#)). These three groups have the potential to establish independent genera. *Rhizoctonia solani* fusarivirus 3 (RsFV3) with a unique monocistronic genome structure is phylogenetically distant from groups I, II, and III and is thus separately categorized into group IV. Likewise, *Agaricus bisporus* virus 10 and 11 (AbV10 and AbV11) are more distantly related to these four groups and are further categorized as group I/II-like viruses in this article owing to the underlying similarity in their genomic structures and sizes.

Currently, there are no criteria for fusarivirus species and genus demarcations. Amino acid identities of fusariviral replication-associated proteins are not greater than 60%, except for *Alternaria alternata* fusarivirus 1 (AaFV1) and *Alternaria brassicicola* fusarivirus 1 (AbFV1), which share identities as high as 86%. Therefore, species demarcation might possess an amino acid percent identity of ≤ 60 for the replication-associated protein that carry the helicase (Hel) and RdRp domains.

Virion Property

None of the currently reported fusariviruses have been shown to form virions. Fusariviruses are considered not to form rigid particles, but to be the so-called nude viruses or capsid-less viruses. This is reasonable because hypoviruses, which are closely related to fusariviruses from an evolutionary standpoint, do not form virions. *Cryphonectria hypovirus* 1 (CHV1), the representative virus in the family *Hypoviridae*, exists in the fungal host cells as a complex of viral replicase and dsRNA (considered a replicative intermediate), which is capsuled in double-layered small lipid vesicles. Such a subcellular structure associated with

fusariviral infection has only been reported as virus-like particle (VLP) for FgV1-DK21. Purified VLPs were aggregates of irregular shaped and sized spherical vesicular structures that were unlike rigid particles. This VLP was shown to strongly associate with viral dsRNAs, thus the structures may stand for replication site of FgV1-DK21. Similar characteristics for other fusariviruses have not been demonstrated.

Genome Organization

Although the type of nucleic acid for fusarivirus genomes is not yet experimentally determined, it is expected to be a positive-sense single-stranded RNA [(+)ssRNA], as is the case for hypoviruses and narnaviruses. The form of the 5' end is unknown, but that of the 3' end is polyadenylated, at least for those complete genomes determined by RACE analyses (Table 1). The length of the RNA genome is 5959–10,776 nucleotides (nts), excluding 3'-poly(A), and the 5' and 3' untranslated regions (UTRs) are in ranges from 5 to 510 nts for the 5' UTR and from 35 to 455 nts for the 3' UTR, excluding poly(A) but including integrated poly(A)-like sequences (Table 1). The replication-associated protein is generally encoded by the largest ORF (ORF1) at the 5' proximal portion, and this is followed by one to three small ORFs in the downstream (Fig. 2). Hel and RdRp domains are present in the replication-associated proteins. This typical genome structure was found in fusarivirus groups I and II. However, viruses in group III have a different genome structure that has a larger sized genome with four coding genes, and the first two and last ORFs encode proteins with no similarities to any proteins in current public databases, whereas the replication-associated protein is encoded by the third ORF (Fig. 2). Additional Hel domain is detectable in the first ORF of viral genomes in group III. Finally, a virus in group IV has a monocistronic nature that encodes only the replication-associated protein. Viruses from groups III and IV have been found only from a basidiomycetous fungus *Rhizoctonia solani*, and these expanded the diversity of fusariviruses.

Fig. 1 Maximum-likelihood (ML) phylogenetic tree of fusariviruses. The ML tree was drawn based on multiple amino acid sequence alignment of RdRp domain (motif 1–8) of fusariviral and hypoviral replication-associated proteins. The branches supported by aLRT (over 0.9) are denoted by dots at nodes. Phylogenetic relationship and genomic structure are taken into account for grouping of fusariviruses.

ORF1 and the second largest ORF (ORF 2, 3, or 4) are commonly encoded by members of classic fusariviruses in groups I and II. These secondly largest proteins exhibit low sequence similarities with each other in general, even between proteins in the same groups. It is notable that the structural maintenance of chromosomes (SMC)-like motif or Spc7 kinetochore protein-like motif was detected in the second largest proteins of fusariviruses in group I but were generally not detected for those of the II and I/II-like groups. This suggests that the viruses in group I have common ancestors.

Gene Expression

The gene expression strategy for the 5' proximal ORF of fusariviruses is largely unknown, but there is some information for downstream ORFs. The ORFs 2, 3, and 4 of FgV1-DK21 are expected to be expressed by two sub-genomic RNAs (Fig. 2). A sub-genomic RNA for ORF2 of *Sodiomyces alkalinus* fusarivirus 1 (SaFV1) is suspected, however, the detected fragment in this instance was vague, so it needs verification. Contrary to this, the possibility to synthesize sub-genomic RNA for ORF2 of *Rosellinia necatrix* fusarivirus 1 (RnFV1) was experimentally denied, suggesting poor commonality of gene expression strategies among the different fusariviruses.

Virus Transmissions

FgV1-DK21, BcFV1, RnFV1, and *Sclerotinia sclerotiorum* fusarivirus 1 (SsFV1) are capable of transmission *via* hyphal anastomosis between virus-donor and virus-recipient strains (horizontal transmission), but others are not confirmed. Similarly, transmission through asexual and sexual spores (vertical transmission) has been observed for FgV1-DK21 and SaFV1. A natural transmission vector for fusariviruses has not yet been discovered.

Fig. 2 Genome composition of representative fusariviruses. Genomic structures of representative fusariviruses are schematically shown. Non-coding regions are indicated by lines and coding regions are shown by rectangles. RdRp and Hel domains are illustrated in the protein coding regions.

Virus–Host Interactions

Among all reported fusariviruses, only FgV1-DK21 exhibited an association with host morphological and physiological changes such as impaired mycelial growth, increased pigmentation, reduced mycotoxin production, and attenuated virulence of its natural host, *F. boothii*. FgV1-DK21 also showed hypovirulence-conferring ability to its heterologous hosts *F. asiaticum*, *F. graminearum*, *F. oxysporum*, and *C. parasitica*. RnFV1, AbFV1, SsFV1, and probably BcFV1 have no impact on the biological properties of their host. The effects of infection by other fusariviruses on host fungal properties are unknown.

FgV1-DK21 is targeted by the host anti-viral RNA silencing or RNA interference. It suppresses this defensive machinery of the host through the repression of key genes in RNA silencing such as *FgDICER2* and *FgAGO1* by the function of ORF2 protein (pORF2). This pORF2 function is similar to the mode of an RNA silencing suppressor encoded by CHV1, p29. Moreover, FgV1-DK21 is known to interact with host cellular proteins. For example, hexagonal peroxisome protein (Hex1) facilitates the replication of FgV1-DK21 *via* a direct interaction with viral RNA. Hex1 is a component of Woronin bodies and plays a crucial role in the asexual reproduction and virulence of host fungus. No other virus–host interactions are characterized for other fusariviruses but FgV1-DK21.

Summary and Future Prospective

The behavior of the representative fusarivirus, FgV1-DK21, has been thoroughly investigated, and some questions particularly related to viral propagation and pathogenicity have been uncovered. However, the basic characteristics of fusariviruses as a genus or a family are still unknown. These include the function of genes encoded by fusariviruses, the gene expression strategies commonly taken by fusariviruses, the 5' end form of fusariviral genomes, and the stable form of fusariviruses in host cells. The use of infectious cDNA clone of fusariviruses will be a powerful tool for understanding of above-mentioned characteristics of fusarivirus. Furthermore, since unique fusariviruses such as RnFV1 (group III), RnFV3 (group IV), and AbV10 (group I/II-like) are reported, more information on the viruses that are most closely related to these are required for a clearer understanding of the evolutionary history and proper taxonomical arrangement of fusariviruses.

History

In 1986, a ~6.3 kbp linear double-stranded (ds) RNA molecule was observed in nucleic acid extracts of *Giardia lamblia* Portland I trophozoites obtained by Dr. D. G. Lindmark of Cleveland State University. Further analysis of this dsRNA showed it to be a genome from a small isometric virus that infects this protozoan. The virus found was named *Giardia lamblia virus* (GLV), referring to the host it infects (Wang and Wang, 1986). *Giardia lamblia*, also known as *Giardia intestinalis* or *duodenalis*, is an anaerobic parasitic flagellate that inhabits the gastrointestinal tract of humans as well as many other mammals. When infecting humans, the parasitic protozoan causes giardiasis, an acute diarrhea that often progresses to chronic carrier-stage in adults and severe malnutrition in children. In chronic form, the parasites adhere to the human gut wall and cause losses in host's digestion and absorption of nutrients. In addition to GLV, there is the *Giardia canis virus* (GCV), a ~6.3 kbp dsRNA virus that infects *Giardia canis*, a protozoan that affects dogs and other canids. In 2001, the GCV was isolated from different strains of *G. canis* and identified by Jianjun *et al.* Unlike *G. lamblia* infection in humans, most *Giardia* infections in dogs are asymptomatic. However, some infected dogs may suffer from acute or chronic diarrhea, weight loss or poor weight gain, in spite of having a normal appetite and, less commonly, vomiting and lethargy (Inger *et al.*, 2007). GLV and GCV probably correspond to the same species, as they share more than 94% of identity between nucleotide sequences, in addition to infecting the same giardia species.

Taxonomy, Classification and Evolution

Currently, according to the International Committee on Taxonomy of Viruses (ICTV), the GLV belongs to the *Giardiavirus* genus of the *Totiviridae* family. *Totiviridae* are characterized by having a dsRNA non-segmented genome and virions with simple structures. Two other genera of dsRNA viruses which also infect protozoa, *Leishmanivirus* and *Trichomonasvirus*, are included in this family, in addition to *Totivirus* and *Victorivirus* comprising viruses that infect fungi (King *et al.*, 2012; ICTV, 2015). Some putative *Totiviridae* viruses are known to infect plants such as maize, the herb *Panax notoginseng* and the red alga *Delisea pulchra* (Chen *et al.*, 2016; Guo *et al.*, 2016; Lachnit *et al.*, 2016). Some others were found in some fish species such as salmon and golden shiner baitfish (Wiik-Nielsen *et al.*, 2012; Mor and Phelps, 2012).

When compared with *Saccharomyces cerevisiae virus L* (ScV), one of the best-known viruses of the *Totiviridae* family, GLV and ScV are similar in many ways, namely: (1) single molecules of genomic dsRNAs of similar sizes; (2) single major capsid polypeptides of similar sizes; (3) virion-associated RdRp with similar amino acid sequence motifs deduced from the genomic sequence, (4) ability to synthesize viral messages from intact virions in vitro; and (5) use of ribosomal frameshifting for the synthesis of viral polymerase. However, the two viruses do not cross-infect and the two dsRNAs do not cross-hybridize in Northern blots (Wang and Wang, 1991). Sequence alignments from GLV cDNAs and those from ScV-L, *Leishmania* RNA virus (LRV) and *Trichomonas vaginalis* virus (TVV) indicate that, despite the similar organization of the viral genomes, GLV share very little overall sequence identity with any of these viruses whose genomic sequences have been completely determined. GLV is therefore not closely evolutionarily related to any of these viruses.

The GCV has not yet been given a completely defined classification. Phylogenetic analysis of RdRp gene sequences demonstrate that GCV is clustered with GLV and piscine myocarditis virus (PMCV) a virus that affects fish myocardial cells, forming the GLV-like clade. Within this same family, the closest related group to GLV-like is the IMNV-like clade, composed of some viruses characterized by affecting arthropods (insects and crustaceans) (Oliveira *et al.*, 2014). The IMNV-like clade was recently proposed as a new genus called Artivirus, based on their distinct genomic organization in relation to other members of the *Totiviridae* family (Dantas *et al.*, 2015). The striking similarity in genome organization and sequence identity as well as the more close phylogenetic proximity of their hosts may indicate that GCV and GLV share a common evolutionary origin; this can be further elucidated with more detailed genetic studies. The phylogenetic relationships among representative members of the *Totiviridae* family regarding RdRp amino acid sequences are shown in Fig. 1.

Host Range and Geographic Distribution

Purified GLV readily infects many virus-free isolate of *G. lamblia* trophozoites, but not any other parasitic protozoa tested, including *Tritrichomonas foetus* and *Trichomonas vaginalis* (Sepp *et al.*, 1994). The virus has also been shown to not infect two transformed human

Fig. 1 Phylogeny of the *Totiviridae* family members calculated from an alignment of RdRp aminoacid sequences using Bayesian inference (Oliveira *et al.*, 2014). Numbers in branch nodes indicate posterior probabilities and colors represent the genera in according to ICTV. The artivirus group was not formally considered as a genus of the *Totiviridae* family to date.

intestinal cell lines (Wang *et al.*, 1988). It is therefore believed that GLV has a rather narrow host range; it probably only infects *G. lamblia* in nature. On the other hand, the cellular host for this virus (*G. lamblia*) parasitizes many mammals other than humans. Viruses that are identical in shape and size to genomic dsRNA and share dsRNA sequence homology with one another have been detected from many *G. lamblia* strains and isolates obtained from humans, guinea pigs, cats, beavers, llamas, and sheep. The human isolates were collected from Belgium, Poland, England, Israel, Ecuador, Puerto Rico, and various states in the USA (Miller *et al.*, 1988).

GCV is known to affect *G. canis* trophozoites. Some studies have reported *G. canis* isolates affecting dogs in Italy, Spain, USA, Australia, China, Canada, Germany and Sardinia, and in wildlife animals such as coyotes from California and African painted dogs reviewed in Thompson and Ash (2016). *Giardia* is common in domestic dogs throughout the world, and is often the most common enteric parasite. Since *Giardia* species are found in almost all parts of the world, affecting organisms in developing as well as developed countries, it is expected that GCV and GLV follows their respective hosts and are also distributed worldwide.

Physical and Biochemical Characteristics

From the 3D structures obtained by transmission electron cryomicroscopy (Cryo-TEM), it can be observed that GLV has a "T=2" type considered icosahedral shaped capsid composed of 120 polypeptide subunits called capsid proteins (CP), and arranged in a "T=1" lattice (Fig. 2(A)). Most of the exterior capsid surface forms a mostly flat raised plateau located at the center of each of the icosahedral 5-fold axes. This plateau is composed by 10 CP subunits. According to analysis of the equatorial sections of the virus (Fig. 2(B)), it is suggested that the CP subunits have prevalence of α -helical secondary structures, with each subunit having a maximum length of approximately 100 Å and very similar tertiary structures (Janssen *et al.*, 2015). The capsid has a single layer with a maximum thickness of approximately 60 Å (median ~40 Å) and outer diameter of approximately 485 Å, which makes GLV the virus with the largest capsid among all totiviruses studied to date, including the IMNV capsid (Janssen *et al.*, 2015).

Fig. 2 Three dimensional structure of GLV virions. (A) Space-filling stereo view of the viral particle based on an icosahedral 2-fold axis (gray point). The colors are correspondent to the radius being dark green outermost and red innermost regions. (B) Central thick section through the virion. Black and white corresponding to highest and lowest densities in the density map, respectively. (Janssen *et al.*, 2015; EMDB - EMD-5948).

There are no studies on GCV capsid physical characteristics yet, but according to its high genomic sequence similarity to GLV, it can be assumed that GCV has a capsid with similar structure.

Regarding the GLV genome array within the virus, it is believed that it is homogeneously distributed within the capsid, except for some points of greatest concentration near the shell. Thus, GLV has a different genome distribution when compared with other totiviruses (Janssen *et al.*, 2015). As the GLV dsRNA can be readily radiolabeled by [32 P]pCp and RNA ligase, this molecule must have a free 3'-OH group at one or both of its 3' end. The exact structure at the 5' end of the dsRNA has not yet been elucidated. It is known that the dsRNA molecule cannot be phosphorylated by T4 polynucleotide kinase, and that the denatured dsRNA molecule can be circularized with T4 RNA ligase. Therefore, the 5' terminus of the GLV genomic dsRNA is probably phosphorylated. Additionally, no covalently linked protein is found at this extremity such as in the case of the poliovirus (Garlapati and Wang, 2005; Furfine *et al.*, 1989; Wang and Wang, 1986).

Both GLV and GCV viruses encode two different proteins, with one being a polypeptide of approximately 100 kDa (P100) that gives rise to the CP subunits, and the viral RNA-dependent RNA polymerase (RdRp), consisting of a 190 kDa polypeptide (Wang *et al.*, 1993). GLV purified virions are good antigens in mice. Polyclonal antibodies raised against whole virions react with P100 in Western blots and can effectively block viral infection in the *in vitro* culture of *G. lamblia* trophozoites. The same antiserum also reacts positively with a minor component of the virion, which is the 190 kDa viral RdRp. Indeed, GLV-encoded RdRp activity has been detected in the infected cell extract as well as the purified GLV fractions. Antisera raised against synthetic dsRNA only cross-reacts with the viral dsRNA and are not protective against viral infection of *G. lamblia* trophozoites *in vitro*. Giardiaviruses do not contain any lipids, nor is the P100 polypeptide glycosylated (Wang *et al.*, 1988).

Table 1 Structural properties of some small dsRNA viruses

Virus	Shape	Diameter (nm)	Density (gm/ml ⁻¹)	dsRNA (μm)	dsRNA (kbp)	Capsid protein (kDa)
GLV	Isometric	48.5	1.368	1.50	6.3	98
GCV	Isometric	48.5 ^a			6.3	98

Abbreviations: GLV, *Giardia lamblia* virus; GCV, *Giardia canis* virus; TVV, *Trichomonas vaginalis* virus; LRV, *Leishmania RNA* virus; ESV, *Eimeria stiedae* virus; ScV-L, *Saccharomyces cerevisiae* virus L; UmV-P1, *Ustilago maydis* virus; IMNV, Infectious myonecrosis virus; HvV190S, *Helminthosporium victoriae* virus 190S.

Experiments in which *Trichomonas vaginalis* virus 1 (TVV1) and GLV virions were exposed to different temperatures and pHs showed that the GLV is more thermoresistant than the TVV1 virions. In addition to GLV being able to mediate transcription through a wide pH range, it has maximum transcription efficiency at pHs close to 8.0, while TVV1 virions mediate transcription in a narrower pH range with maximum efficiency at pHs near 6.5. These characteristics correspond to different intracellular conditions encountered in their respective hosts, since *T. vaginalis* trophozoites ideal growth occurs under more acidic conditions (pH < 6.5) than *G. lamblia* trophozoites (pH > 7) (Janssen *et al.*, 2015). The structural properties of the GLV and GCV comparing with other totiviruses are shown in Table 1.

Organization and Molecular Biology of GLV and GCV dsRNA Genomes

The 6277 bp GLV and 6276 bp GCV dsRNA genomes contain only two large open reading frames (ORFs), both on the same RNA strand. The two genomes share nucleotide identity higher than 94%, presenting the most number of single nucleotide variations at ORF1 region. GLV and GCV first ORFs (nts 367–3027 and 367–3030, respectively) encode the precursor polypeptide for the capsid protein. Thirty-two amino acid residues from the N-terminus of this precursor protein are apparently removed by a cellular cysteine protease before the processed capsid protein is assembled into the GLV virion (Yu *et al.*, 1995; Chen *et al.*, 2007; Liu *et al.*, 2008).

The second ORF (nts 2805–5978 and 2808–5981 for GLV and GCV, respectively) is encoded in –1 frame (in relation to ORF 1), and the two ORFs overlap by 220 bp. RdRp motifs have been found in many ORF2 from different totiviruses (Oliveira *et al.*, 2014; Dantas *et al.*, 2015). It is now known that the GLV RNA polymerase (190 kDa) is synthesized as a fusion protein of ORFs 1 and 2 at a level that is 2–5% of P100. Apparently, ribosomes carrying the growing nascent polypeptide chain are stalled when they encounter the pseudoknot structure residing within the 220 nt overlap of these two ORFs. At a 2–5% frequency, the ribosomes slip back one reading frame and proceed to translate ORF 2 as the C-terminus of a fusion protein. The ability of this GLV overlap fragment to induce a –1 ribosomal frameshift has been demonstrated in a reporter system in yeast (Wang *et al.*, 1993). The schemes of GLV and GCV genomes are shown in Fig. 3.

Flanking the 5' and 3' ends of the two ORFs are two untranslated regions. For the GLV, the 5' and 3' UTRs have 367 and 294 nts respectively, and in GCV the corresponding regions have 367 and 298 nts (Wang *et al.*, 1993; Dantas *et al.*, 2015). It was identified that these two regions contain sequence elements that are critical for initiation of transcription and replication of GLV RNA. For example, deletion of a single nucleotide from the 5' terminus of the (+) strand GLV RNA totally abolishes transcription of GLV mRNA. Similarly, deletion or alteration of sequences in these two regions drastically reduces the level of progeny viral RNA (Garlapati *et al.*, 2001; Garlapati and Wang, 2004, 2005).

GLV has been successfully used as a vector for the introduction of foreign genes into *G. lamblia*. When a portion of the GLV genome is replaced with the firefly luciferase gene in a cDNA construct downstream from a T7 promoter, chimeric RNA can be synthesized in vitro using T7 polymerase. *Giardia* cells that are infected with wild-type GLV and electroporated with the chimeric RNA show luciferase activity of a millionfold above background. The chimeric RNA is replicated as dsRNA and packaged into recombinant virions that are shed into the culture supernatant. These recombinant viruses together with wild type GLV can in turn infect naive *Giardia* trophozoites to produce luciferase activity (Garlapati *et al.*, 2001). The list of foreign genes tested in this system include gene encoding neomycin phosphotransferase, hygromycin phosphotransferase, and green fluorescent protein. Moreover, they can be delivered and expressed at high levels (Yu *et al.*, 1996). Inclusion of a nts 368–631 fragment in the coding region of P100, such as the N-terminus of a fusion protein with the foreign gene product has been shown to enhance translation level by 5000-fold (Yee and Nash, 1995). This region therefore may contain elements that can promote interaction between GLV mRNA and ribosomes of *G. lamblia*.

Giardiavirus mRNA is neither capped nor adenylated. Translation is initiated at an internal ribosomal entry site (IRES) in the mRNA consisting of a 253 nt segment in the 5' untranslated region (5' UTR) and a 264 nt stretch in the ORF immediately downstream from the 5' UTR. The initiation codon is localized at the center of an unstructured 31 nt segment flanked by complex

Fig. 3 Organization of the *Giardia lamblia* virus and *Giardia canis* virus dsRNA genomes.

secondary structures in the 5' UTR and the ORF of the IRES. The precise position of the initiation codon is critical for translation initiation. It also suggests a direct recruitment of the 40 S small ribosomal subunit to the initiation codon without ribosomal scanning, a process that is known to be absent from the translation machinery in *Giardia* (Garlapati and Wang, 2005).

Infection and Replication

GLV infects susceptible isolates of *G. lamblia* very efficiently. It has been estimated that demonstrable infection can be achieved at an infection multiplicity as low as 10 GLV particles per cell (Miller *et al.*, 1988). The virus is not observed in *Giardia* cysts, and is not known to occur during the transition between cyst and trophozoite. The exact mode of viral entry into the cell has not yet been elucidated. With infection course, it is observed that the viruses enter into susceptible parasite cells via endocytosis, where the peripheral lysosomal vacuoles serve as virus translocation ports to cytoplasm (Tai *et al.*, 1993). Sepp *et al.* (1994) suggests that this internalization is mediated by endocytosis receptors. However, a number of virus-free *G. lamblia* strains have been found to be resistant to GLV infection. When trophozoites of these strains are electroporated with the single-stranded GLV RNA (ssRNA), they become infected by GLV and can support and complete the replication cycle, producing progeny virions that are fully infective to sensitive strains (Furfine and Wang, 1990). It is expected that these receptors are present on the surface of cells susceptible to the virus, are responsible for binding and internalizing the virus, and are absent in resistant protozoa. GLV is the only known protozoan viruses which can be efficiently transmitted by extracellular pathways, indicating that virion have the necessary protein machinery to efficiently mediate the entry.

Using purified GLV to infect a virus-free *G. lamblia* WB strain, in situ hybridization was used to show that dsRNA replication was first detected in the cytoplasm. Toward the late stage of infection, viral dsRNA was found to spread into the twin nuclei of the infected flagellate. Transmission electron microscopic examination of thin sections of infected cells at stationary phase also reveals paracrystals of virus-like particles in the nuclei (Fig. 4). It has been estimated that an infected cell may harbor as many as 10^5 GLV particles without lysis. Meanwhile, mature and infectious GLV particles begin to appear in the supernatant of *Giardia* culture medium 42 h after infection (Wang and Wang, 1986; Tai *et al.*, 1991). It is not known whether a specific cellular process is involved in the GLV release into the culture supernatant, although cell lysis has not been observed as a consequence of viral infection. The viruses are excreted into the culture medium and can infect these same isolates of many other free *Giardia*. The *G. lamblia* growth rate of newly infected cells decreases with increasing infection multiplicity. As the ratio of the infecting virus to cell increases, the percentage of the non-adhering (non-dividing) trophozoites also increases. However, in established infected cell lines or at moderate multiplicity of infection (<1000), the infected cell assumes normal appearance and maintains the same growth rate as its uninfected counterpart. Furthermore, GLV infection persists indefinitely throughout repeated subcultures (Wang and Wang, 1986; Miller *et al.*, 1988).

It is suggested by Janssen *et al.* (2015) that GLV can transcribe its genome inside the icosahedral capsid right after entry into the *G. lamblia* cytoplasm. The genome is transcribed by the RdRp domain of the CP/RdRp subunit(s) still inside the "T=2" icosahedral capsid, and the plus-strand transcripts are then released from the particle, allowing translation of the GLV proteins and packed into nascent progeny virions. This strategy is thought to be common to all dsRNA viruses, possibly except for Bimaviruses (Luque *et al.*, 2009).

Fig. 4 Thin section of a giardiavirus-infected cell. C, cytoplasm; N, nuclear envelope; F, flagella; D, ventral disk; V, aggregates of virus particles.

In addition to the GLV 6.3 kbp genomic dsRNA, a single stranded RNA (ssRNA) of identical length that is homologous to only one of the two strands of GLV dsRNA is also found in the GLV-infected cellular extract (Furfine *et al.*, 1989). Studies of the infection time course showed that, in contrast to GLV dsRNA which increases steadily from 23 to 141 h after infection, ssRNA becomes detectable at about the same time, peaks at 42–50 h after infection, then gradually declines. Electroporation of gel-purified ssRNA into the uninfected WB cells resulted in the recovery of dsRNA from the cell extract and infectious GLV particles in culture supernatant, demonstrating that SS is the viral messenger RNA as well as the full-length replicative form of the viral genome (Furfine and Wang, 1990). Nucleotide sequence analysis of GLV cDNA clones also verifies that it is the ssRNA strand that encodes the large ORFs. There is no subgenomic viral RNA detected inside the infected cell. The RNA products synthesized in vitro by the virion-associated RdRp are homologous to ssRNA and complementary to the negative strand. Transcription of viral message therefore must proceed conservatively by utilizing the dsRNA as its template.

Studies performed by Cao *et al.* (2009) indicate that GCV may be released by budding. TEM micrographs of *G. canis* infected with GCV show a gradual process of budding formation during the virus discharge. Alternatively, they suggest that the virus may also be released by lysis of infected trophozoites because of the apparent loss of the cell membranes when the trophozoites were crowded.

Since the successful cloning of the full length cDNA from dsRNA template of GLV (Wang *et al.*, 1993), the modified giardiavirus RNA has been used as a genetic tool for the study of possible intervention and pathogenesis (Liu *et al.*, 2005). Similarly, GCV has been used to construct a stable transfection system which was used to stably transfect trophozoites of *G. canis* (Chen *et al.*, 2007; Liu *et al.*, 2008). Liu *et al.* (2008) successfully established a stable transfection system based on the GCV with stable expression of green fluorescent protein in *G. canis*, while Chen *et al.* (2007) cloned a hammerhead ribozyme flanked with various lengths of antisense Krr1 RNA into a viral vector derived from GCV genome. In the same study, RNA plasmid transcripts showed high cleavage activities on *G. canis* Krr1 mRNA in vitro causing a decrease in its levels and leading to trophozoite deformation. The extent to which a person is affected by giardiasis varies widely. The outcome of the severity of parasitic infection depends on many variables derived not only from the parasite, but also from the human host. Attempts at correlating the presence or absence of GLV with the severity of giardiasis have been inconclusive, and we still do not know the role GLV might play in the delicate balance of the host–parasite interaction, if any.

This is an update of D.L. Nuss, Hypoviruses, In Encyclopedia of Virology (Third Edition), edited by Brian W.J. Mahy and Marc H.V. Van Regenmortel, Elsevier Ltd., 2008, doi:10.1016/B978-012374410-4.00406-4.

Glossary

Anastomosis The fusion of fungal hyphae resulting in exchange of cytoplasmic material and hypovirus transmission.

Hypovirulence Virus-mediated attenuation of fungal virulence.

Vegetative incompatibility A system controlled by at least six genetic loci that determines the ability of two fungal strains to undergo anastomosis.

Introduction

The discovery of hypoviruses, a group of RNA viruses that reduce the virulence (hypovirulence, see article on Hypovirulence; volume 3, this encyclopedia) of the chestnut blight fungus *Cryphonectria parasitica*, stimulated intensive research into the potential of using fungal viruses for biological control of fungal diseases. Documented examples of virus-mediated hypovirulence have been reported for fungal diseases of plants that range from trees to turfgrass and involve mycoviruses which include representatives from the *Totiviridae*, *Chrysoviridae*, *Reoviridae*, *Narnaviridae* and *Hypoviridae* (the hypoviruses). However, the hypoviruses remain the most thoroughly studied of the hypovirulence-associated viruses, primarily due to several significant advances in hypovirus molecular biology.

In 1977, Peter Day and co-workers at the Connecticut Agricultural Experiment Station reported that hypovirulent *C. parasitica* strains harbor double stranded (ds) RNAs, providing the first indication of the nature of cytoplasmic elements responsible for the hypovirulence phenotype. Subsequent surveys of dsRNAs associated with different North American and European hypovirulent strains revealed considerable variations in concentration, number and size of dsRNA components. By the late 1980s, it was clear that a detailed molecular analysis of the dsRNAs associated with a single hypovirulent strain was required to bring some measure of order to the mounting confusion generated by such surveys. This resulted in the cloning and complete sequence determination of the prototypic hypovirus, now designated CHV1-EP713, in 1991. This milestone was followed in 1992 by the construction of an infectious full-length (12,712 bp) cDNA clone of CHV1-EP713 RNA by Choi and Nuss. This development furnished direct evidence that hypoviruses are indeed the causative agents responsible for transmissible hypovirulence and provided the means for facile manipulation of the hypovirus genome. Current interest in hypoviruses extends past biological control potential to their utility as unique experimental tools for probing fundamental processes underlying fungal pathogenesis and mycovirus-fungal host interactions.

Taxonomy and Genetic Organization

Hypoviruses are classified within the family *Hypoviridae*, consisting of the genus *Hypovirus* and four species with the exemplar strains designated as *Cryphonectria parasitica* hypovirus 1–4 (CHV1–CHV4). Hypovirus taxonomy is not based on virus structure, since this group of viruses does not encode a coat protein, but on genome organization, sequence similarity and symptom expression. Hypovirus genetic information is found predominantly as dsRNA associated with membrane vesicles ranging in diameter from 50 to 80 nm. As observed for fungal viruses generally, hypoviruses exhibit no extracellular phase in their life cycle. Infections cannot be initiated by inoculation with an infected cell extract or enriched fractions. Instead, these viruses are transmitted by cytoplasmic mixing as a result of fusion (anastomosis) between vegetatively compatible strains or to a variable degree in asexual spores (conidia).

The hypoviruses were assigned the designations CHV1–CHV4 in the order in which their genome sequence was completed. The primary nucleotide sequence for the coding strand of the prototypic member of the genus *Hypovirus*, CHV1-EP713, specifies two large open reading frames (ORFs) designated ORF A and ORF B (Fig. 1). A second closely related member, CHV1-Euro7, has the same organization and shares approximately 90% identity at the nucleotide level with CHV1-EP713. The type member of the *Cryphonectria parasitica* hypovirus 2, CHV2-NB58, shares only about 60% nucleotide sequence identity with CHV1-EP713 and lacks a portion of ORF A that, for the CHV1, encodes a functional cis-acting cysteine protease. Sequenced members of *Cryphonectria parasitica* hypovirus 3 and 4, CHV3-GH2 and CHV4-SR2, respectively, are several kb shorter than CHV1-EP713 and CHV2-NB58, ~9.2–9.8 kb versus 12.5–12.7 kb, contain a single large ORF rather than two ORFs and are both more distantly related phylogenically to CHV1-EP713 than CHV1-EP713 is to CHV2-NB58.

Unassigned hypovirus-related viruses have been reported to infect filamentous fungi other than *C. parasitica*, including *Sclerotinia sclerotiorum*, *Valsa ceratoperma*, *Phomopsis longicolla*, *Fusarium* ssp., *Macrophomina phaseolina* and *Agaricus bisporus*.

Fig. 1 Genetic organization of sequenced hypovirus genomes representing the four species that comprise the genus *Hypovirus*, family *Hypoviridae*. Amino acid identity levels for coding regions of the two sequenced members of *Cryphonectria hypovirus 1* species, CHV1-EP713 and CHV1-Euro7, are indicated between representations of the two viral genomes. Protein coding regions homologous to CHV1-EP713 encoded p29, p40, p48, polymerase and helicase are color coded. The magenta regions represent a short conserved cysteine rich domain. Note that the genomes of CHV3-GH2 and CHV4-SR2 contain a single ORF. Modified from Dawe, A.L., Nuss, D.L., 2001. Hypoviruses and chestnut blight: Exploiting viruses to understand and modulate fungal pathogenesis. Annual Review of Genetics 35, pp. 1–29, with permission from Annual Reviews.

Fig. 2 Expression strategy for prototypic hypovirus CHV1-EP713. The CHV1-EP713 coding strand consists of 12,712 nucleotides excluding a poly(A) tail, and contains two major coding domains designated ORF A and ORF B. Details are discussed in the text. Modified from Dawe, A.L., Nuss, D.L., 2001. Hypoviruses and chestnut blight: Exploiting viruses to understand and modulate fungal pathogenesis. Annual Review of Genetics 35, pp. 1–29, with permission from Annual Reviews.

Hypovirus Gene Expression Strategy

Although hypovirus genetic information is readily recovered from infected cultures as linear dsRNA, the absence of a discrete virus particle and an extracellular infection phase presents some difficulties in precisely defining the hypovirus genome. Synthetic copies of the coding strand are infectious by electroporation into fungal spheroplasts and phylogenetic analyses suggests a common ancestry with the positive strand RNA plant potyviruses. Thus, one could consider hypoviruses as having a positive strand RNA genome and the dsRNA as representing accumulated replicative form RNA. Irrespective of this complication, direct analysis of hypovirus dsRNAs, cDNA cloning studies and *in vitro* translational analyses has provided the following view of genetic organization and expression strategies for the prototypic hypovirus CHV1-EP713 shown in Fig. 2. One strand contains a 3'-poly A tail while the complementary strand contains a 5' poly U tract. All of the CHV1-EP713 coding information appears to reside within two contiguous ORFs on the 12,712 nt long polyadenylated strand. Translation of ORF A is facilitated by an internal ribosome entry site (IRES) located at the end of the 5'-non-coding region and extending into the beginning of the coding domain. ORF A encodes two polypeptides, p29 and p40, that are released from a polypeptide precursor, p69, by an autoproteolytic event between Gly-248 and Gly-249, mediated by a cysteine-like protease catalytic domain located within p29. ORF B has the capacity to encode a polypeptide of 3165 amino acids and contains unmistakable RNA-dependent RNA polymerase and helicase motifs. Proteolytic processing of only a portion of the ORF B polypeptide has been elucidated in the form of the autoproteolytic release of a 48 kDa

protein, p48, from the N-terminus. This cleavage event occurs between Gly-418 and Ala-419 and is catalyzed by essential residues Cys-341 and His-388 within p48. The junction between ORF A and ORF B is defined by the sequence 5'-UAAUG-3', in which the UAA portion clearly serves as the termination codon for ORF A and the AUG portion is thought to serve as the initiation codon for ORF B. The mechanism by which ribosomes transition through the junction involves coupled termination/reinitiation. This unusual pentanucleotide sequence is found at the ORF A/ORF B junction for all confirmed strains of *Cryphonectria hypovirus 1*. There is clearly a need for additional fine detailed mapping of the processing cascades for hypovirus-encoded polyproteins.

The genome of CHV2-NB58, the type strain of *Cryphonectria hypovirus* 2, also consists of a two ORF configuration with a UAAUG junction (Fig. 2). However, ORF A lacks the p29 papain-like catalytic or cleavage sites and directs the translation of a 50-kDa protein product. ORF B of CHV2-NB58 does contain a p48 homologue, p52. The N-terminal portion of the single ORF of type strain CHV3-GH2 (*Cryphonectria hypovirus* 3), contains a protease, p32, with similarity to p29. A putative protease domain has been identified at the N-terminal portion of the type strain CHV4-SR2 of *Cryphonectria hypovirus* 4, but protease cleavage has not been demonstrated.

In most hypovirus-infected *C. parasitica* isolates, the full-length viral dsRNA is accompanied by a constellation of shorter dsRNA species. These ancillary dsRNAs appear to be generated by internal deletion events, are replicated only in the presence of the full-length viral RNA and are not associated with any function or phenotypic effect.

Hypovirus Functional Domains

Hypovirus-encoded symptom determinants and important expression and replication elements have been mapped (**Fig. 3**) by a combination of approaches that include (a) the construction of recombinant chimeras from hypoviruses that differ in their influence on host phenotype, (b) mutagenesis of a hypovirus infectious cDNA clone and (c) cellular expression of viral coding domains independent of virus infection.

In analogy with plant viruses, CHV1-EP713 and CHV1-Euro7 can be viewed as severe and mild hypovirus isolates, respectively. Although these two CHV1 isolates cause quite different phenotypic changes in their fungal host, they share a high level of sequence similarity that has allowed the construction of viable chimeric viruses to begin mapping the determinants responsible for the differences in phenotypic changes.

Differences in host colony morphologies were found to map to a region extending from a position just downstream of the p48 coding domain (map position 3575) to map position 9879, with clear indications of multiple discrete determinants. More specifically, the region extending from position 3575 to 5310 was able to confer a CHV1-EP713-like colony morphology when inserted into a CHV1-Euro7 genetic background. The CHV1-EP713 p48 coding region was found to be a dominant determinant contributing to suppression of asexual spore formation on the canker face. In a separate study, p48 was shown to have the unusual property of being required for the initiation but not the maintenance of viral RNA replication.

The chimeric hypoviruses also proved to be very useful reagents when coupled with a pathway specific promoter/reporter system to map viral determinants responsible for altering host G-protein/cAMP-mediated signaling. A common undesired side effect of hypovirus-mediated virulence attenuation is a significantly reduced ability of the fungal host to colonize and produce spores on the corresponding plant host. This reduces the ability of hypovirulent fungal strains to persist and spread through the ecosystem. Thus, from a practical perspective, a better understanding of the nature of viral symptom determinants and their relative effects on specific regulatory pathways and expression of gene clusters provides the means for a more rational approach for engineering hypoviruses that exhibit a desired balance between virulence attenuation and ecological fitness.

Additional insights into the functional role of viral coding regions were indirectly provided during efforts to develop hypoviruses as gene expression vectors. The nucleotide sequence corresponding to the first 24 codons of p29 was found to be required for viral replication, while the remaining 598 codons of ORF A, including all of the p40 coding region, was found to be dispensable. The 24 N-terminal codons were subsequently shown to function as an essential element of an internal ribosome entry

Fig. 3 Map of CHV1-EP713 symptom determinants and essential/dispensable replication elements as described in the text. Modified from Dawe, A.L., Nuss, D.L., 2001. Hypoviruses and chestnut blight: Exploiting viruses to understand and modulate fungal pathogenesis. *Annual Review of Genetics* 35, pp. 1–29, with permission from Annual Reviews.

site (IRES) involved in ORF A translational initiation. Substantial alterations were also tolerated in the pentanucleotide UAAUG that contains the ORF A termination codon and the overlapping ORF B initiation codon. For example, replication competence was maintained following either a frame-shift mutation that caused a two-codon extension of ORF A or a modification that produced a single-ORF genomic organization. Further characterization of p40 revealed a role as an accessory function in viral RNA amplification with a functional domain extending from Thr(288) to Asn(313) and a role of a p40 coding domain just upstream of the UAAUG pentamer in coupled translational termination/reinitiation.

Expression of the CHV1-EP713 encoded papain-like protease, p29, in the absence of virus infection was shown to cause a subset of phenotypic changes exhibited by CHV1-EP713-infected strains, e.g., a white phenotype (reduction in orange pigmentation), reduced asexual sporulation and a slight reduction in the production of fungal laccase activity. By deleting all but the first 24 N-terminal codons of p29 in the context of the CHV1-EP713 infectious cDNA clone (mutant virus Δ p29), it was also possible to show that the p29 protein is dispensable for viral replication and to demonstrate a near restoration of orange pigment production and a moderate increase in conidiation levels relative to wild-type CHV1-EP713-infected fungal colonies. Deletion of p29 had no effect on virus-mediated virulence attenuation. A gain-of-function analysis involving progressive repair of the Δ p29 mutant was also devised to map the p29 symptom determinant domain to a region extending from Phe-25 to Gln-73. When expressed from a chromosomally integrated cDNA copy, p29 elevated RNA accumulation and vertical transmission (through conidia) of the Δ p29 mutant virus to levels observed for wild-type CHV1-EP713. Additional mutational studies indicated a linkage between p29-mediated changes in host phenotype in the absence of virus infection and p29-mediated *in trans* enhancement of viral RNA accumulation and transmission.

The multifunctional nature of p29 was extended to include suppressor of RNA silencing both in the natural fungal host and in a heterologous plant system. This activity was predicted based on similarities between p29 and the well-characterized potyvirus-encoded suppressor of RNA silencing HC-Pro and provided the first circumstantial evidence that RNA silencing in fungi may serve as an antiviral defense mechanism, a well-established function in plants.

Anti-Hypovirus Defense Mechanisms

Direct evidence for RNA silencing as a defense against hypovirus infection was obtained by systematic disruption of the *C. parasitica*-encoded Dicer and Argonaute genes, core RNA silencing pathway components. Dicers nucleases recognize and process viral double-stranded and structured RNAs into small 21–24 nt long RNAs, termed virus-derived small (vs) RNAs. With the aid of an Argonaute family protein, the vsRNAs are incorporated into an effector complex termed the RNA-induced silencing complex (RISC). One strand of the vsRNA is then degraded and the remaining strand guides the effector complex to the cognate viral RNA, which is then cleaved by the Argonaute-associated RNase H-like activity. Disruption of the two Dicer-like genes and the four Argonaute-like genes found in *C. parasitica* resulted in no observable phenotypic changes. However, infection of the mutant strains with hypoviruses or an unrelated mycoreovirus MYRV1-Cp9B21 resulted in increased viral RNA levels and severe virus-induced symptoms only in the Δ dcl2 and Δ agl2 mutants. The dependence on a single Dicer and a single Argonaute for antiviral defense in *C. parasitica* contrasts with dependence on multiple Dicer and Argonaute genes for antiviral defense in plants.

Dicer *dcl2* transcript levels were shown to increase 10–12-fold in an *agl2*-dependent manner, following infection by Cryphonectria hypovirus 1 (CHV1) and to exhibit super-induction (over 30-fold) after infection by CHV1- Δ p69, lacking the p29 viral suppressor of RNA silencing. A genetic screen subsequently identified the conserved transcriptional activator SAGA (Spt-Ada-Gen5 acetyltransferase) as a regulator of this up-regulation. Mutational analysis demonstrated that the SAGA-associated histone acetyltransferase (HAT) activity, but not the histone deubiquitinase (DUB) activity, was the major influence on the SAGA-mediated induction of *dcl2* transcription following virus infection.

Early efforts to characterize hypovirus RNA at the molecular level revealed the accumulation of internally deleted defective interfering (DI) RNAs generated from full-length viral RNA by a combination of deletion and recombination events. Recombination-mediated deletion of non-viral nucleotide sequences also limited efforts to use recombinant hypoviruses to express foreign genes. Interestingly, DI RNAs failed to accumulate and recombinant hypovirus expression vectors were shown to be stable in the Δ dcl2 and Δ agl2 mutants. The combined results were the first to link an RNA silencing pathway to viral RNA recombination and are of potentially broad significance with possible applications for stable production of biologicals by mycovirus-based vectors.

While the RNA silencing pathway serves as an anti-viral defense at the cellular level, the *C. parasitica* vegetative incompatibility (*vic*) non-self recognition system provides antiviral defense at the population level. In the absence of an extracellular phase to their replication cycle, mycoviruses rely on anastomosis (fusion of hyphae) as a major avenue for horizontal transmission. The fungal *vic* system restricts mycovirus transmission due to incompatible reactions triggered when genetically distinct, *vic*-incompatible individuals of the same species interact. This reaction results in localized programmed cell death along the zone of contact, limiting transmission of viruses and other cytoplasmic elements.

The *C. parasitica* *vic* system is controlled by at least six di-allelic loci, designated *vic1*, *vic2*, *vic3*, *vic4*, *vic6* and *vic7*, that were recently identified and characterized at the molecular level. Gene disruption analysis formally confirmed that five of the six loci contribute to restriction of virus transmission. An allelic difference at *vic4* does not restrict virus transmission. Systematic disruption of four of the five virus-restricting *vic* gene alleles was reported to engineer a super hypovirus donor (SD) strain formulation that was able to transmit hypovirus under laboratory conditions to uninfected strains that were heteroallelic at one to five of the virus-restricting *vic* loci. These results predict that the SD formulation could circumvent *vic*-imposed restrictions to virus

transmission by serving as an effective vector to introduce hypovirus into natural field strains with widely diverse *vic* genotypic combinations of the six defined diallelic *vic* loci. This property should find application in efforts to integrate biological control with increased disease resistance derived from backcross breeding programs or transgenes for effective woodland restoration of the American chestnut.

Glossary

Ascomycetous fungi Fungi phylogenetically classified into the division Ascomycota, which is characterized by the formation of spores in asci in the fungal life cycle.

Hypovirulence Mycovirus-mediated attenuation in virulence of phytopathogenic fungi to plants.

Mycoviruses Viruses that infect fungi.

Ribosomal-1 frameshifting A translation mechanism of the polycistronic gene, in which ribosome slip through one

nucleotide on a slippery or shifty heptamer (typically “X XXY YYZ”, where the same letter represents the same set of nucleotides), followed by an RNA element forming a pseudo-knot or stem-loop structure.

Spheroplasts Isolated cells enclosed in partially digested cell walls.

T = 1 icosahedral symmetry Symmetry of capsid composed of 60 subunits, which forms 12 pentameric capsomeres.

Introduction

Rosellinia necatrix megabirnavirus 1 (RnMBV1, species *Rosellinia necatrix megabirnavirus 1*, genus *Megabirnavirus*, family *Megabirnaviridae*) was first isolated in 2009 from a phytopathogenic ascomycetous fungus, *Rosellinia necatrix*, which is the causal agent of white root rot disease and causes severe damage to many perennial crops. The virus was discovered during routine screens for mycoviruses conferring hypovirulence to the host fungus as part of a project led by Dr. Naoyuki Matsumoto that was aimed at virocontrol, a form of biocontrol using viruses that was initiated in the 1990s in Japan. The research group was inspired by the success of the virocontrol of chestnut blight disease using hypoviruses in Europe. RnMBV1 inhibits growth of and reduces virulence of *R. necatrix*. It is composed of a bipartite double-stranded RNA (dsRNA) genome that is encapsidated in non-enveloped spherical particles that are 52 nm in diameter. Among the established taxa to which multipartite dsRNA viruses are assigned, namely the family *Reoviridae*, *Partitiviridae*, *Chrysoviridae*, *Quadriviridae* and *Megabirnaviridae*, and the genus *Botybirnavirus*, the polycistronic gene encoding strategy is observed only in megabirnaviruses. Thus, in 2011 RnMBV1 was assigned to the newly established taxa, the genus *Megabirnavirus* in the family *Megabirnaviridae*. “Birna-” is derived from bipartite segments and “Mega-” means much greater genome size (approximately 16 kbp) than those of *birnaviridae* and *pico-birnaviridae* (approximately 6 kbp and 4 kbp, respectively). The family *Megabirnaviridae* is currently comprised of a single genus, *Rosellinia necatrix megabirnavirus 1*, to which only the type member is assigned. Besides, several mycoviruses that are phylogenetically related to and share common properties with RnMBV1 have been reported in the last five years, although they have not been officially assigned to the taxa. In this article the properties of RnMBV1 are summarized and compared with those of related viruses.

Virion Properties

The megabirnavirus genome is encapsidated in non-enveloped spherical particles that are 52 nm in diameter (Fig. 1). Virus particles contain a bisegmented dsRNA genome (Fig. 2). Each segment seems to be packaged separately, based on the two following observations: first, purified virus particles include an unequal and variable molar ratio of two dsRNA segments; second, artificial virion transfection into hosts can trigger the emergence of mutants that completely lack dsRNA2. Virions are constructed from the major capsid protein (CP), which is 136 kDa. Purified virions also contain minor CP-RdRP fusion proteins that are greater than 250 kDa (Fig. 1). Purified virions can be introduced to spheroplasts from the natural and experimental fungal hosts, *R. necatrix* and *Cryphonectria parasitica*, respectively.

Genome Organization

The megabirnavirus genome consists of two segments, termed dsRNA1 and dsRNA2 (Fig. 2, Table 1). Each segment has two non-overlapping putative open reading frames (ORFs). The larger segment (dsRNA1, 8.9 kbp) contains ORF1 and ORF2, which encode the major structural protein (CP, P1) and RNA-dependent RNA polymerase (RdRP, P2), respectively. The smaller segment (dsRNA2, 7.2 kbp) contains ORF3 and ORF4, encoding hypothetical proteins P3 and P4, respectively, with unknown function. Both genome segments contain an extremely long 5'-untranslated region (UTR) of over 1.6 kbp. 3'-UTRs of both segments are relatively short (< 0.4 kbp). The terminal sequence of 5'-UTR and 3'-UTR is conserved between both segments. The 5'-terminal 24-bp and 3'-terminal 8 bp-sequence are strictly conserved between the RnMBV1 segments (Fig. 3).

Genome Expression and Replication

Replication of megabirnavirus is predicted to occur in virus particles, as is the case for other dsRNA viruses. The fact that purified virions include RdRP-CP fusion proteins supports this hypothesis. RdRP-CP fusion products are likely translated from bicistronic transcripts of dsRNA1 via ribosomal-1 frameshifting. ORF2 encoding RdRP lies downstream -1 reading frame of CP-encoding ORF1 on the same positive strand (Fig. 2). There is a putative slippery sequence (5'-A AAA AAC-3') immediately upstream of the stop codon for ORF1. There is also a sequence element that potentially forms pseudo-knot/stem-loop structures upstream and downstream of the ORF1 stop codon.

The long 5'UTR of megabirnavirus contains multiple mini-ORFs and hypothetical internal ribosomal entry sites (IRESs). It remains to be experimentally determined whether translation initiation of ORF1 and ORF3 is mediated by these IRESs. It is also unknown whether or how ORF4 is expressed.

Virion Structure

The three-dimensional structure of RnMBV1 was determined by cryo-electron microscopy at 15.7 Å resolution (Fig. 4). Each capsid is composed of 60 homodimers of CP with *T* = 1 icosahedral symmetry like many other fungal dsRNA viruses. A distinct features of virions of megabirnavirus is putative 120 large protrusions on the surface of capsid shell. The protrusions are observed, with a width of ~45 Å and a height of ~50 Å, around icosahedral two- and threefold axes, while trenches are observed around icosahedral fivefold axes.

Multiple sequence alignments of the 5' UTRs (a) and 3' UTRs (b) of two dsRNA segments were performed with ClustalW2. Asterisks indicate the position where an identical base is present. Accession no. of sequence is listed in Table 1.

Fig. 4 Three-dimensional cryo-electron microscopy reconstruction of virions of RnMBV1 at a resolution of 15.7 Å. The surface representation of RnMBV1 particles viewed along an axis with fivefold symmetry (a) or twofold symmetry (b). Molecular boundaries of the A and B subunits are drawn with continuous orange and red, respectively. Courtesy of Naoyuki Miyazaki.

The inner and outer diameter of RnMBV1 capsid shell, excluding the protrusions, are 190 and 210 Å, respectively. For *Saccharomyces cerevisiae* virus L-A in the family *Totiviridae*, grooves on capsid shells could play an enzymatic role in cap snatching from cellular mRNA. An investigation into the functions of the protrusions exposed on the surface of RnMBV1 virions could be interesting future work.

Biological Properties

The biological traits of megabirnavirus have been extensively studied in the RnMBV1-W779 strain. RnMBV1 persistently infects the natural host *R. necatrix* via inter-cellular cytoplasmic exchange and cell division. Furthermore, RnMBV1 can be horizontally transmitted to compatible fungal hosts and inhibits the growth of *R. necatrix*, which is a devastating phytopathogen that causes white root rot in fruit trees. Due to the hypovirulence it confers to *R. necatrix* (Fig. 5), RnMBV1 is regarded as a potential biological control agent for plant disease management.

RnMBV1 can be inoculated into the ascomycetous fungus *Cryphonectria parasitica*. *C. parasitica* is not only the causal agent of chestnut blight disease, but it is also a model fungus for studying of virus-virus and virus-host interactions. RnMBV1 is also responsible for growth inhibition and hypovirulence of *C. parasitica*, as well as *R. necatrix*. In a *C. parasitica* mutant ($\Delta dcl2$) that lacks a component of antiviral RNA interference (RNAi) machinery (dicer-like protein 2), accumulation of RnMBV1 is ~20 fold higher than in the wild type. The symptoms induced by RnMBV1 are promoted in $\Delta dcl2$. These observations suggest that RNAi in

Fig. 5 Mycelial growth of virus-carrying field strain W779 and virus-cured isogenic strain W1015 of *R. necatrix*. (a) Colony morphology of *R. necatrix* strains W779 and W1015. The fungal strains, W779 and W1015, were grown on PDA for 5 days in the dark and photographed. (b) Mycelial growth on apple rootstocks. Twigs of Japanese pear (1.5 cm long) were placed for 3 weeks on 5-day-old PDA cultures of the fungal strains W779 and W1015. Japanese pear twigs covered with mycelia of each fungal strain were fixed on stems of apple rootstocks (*M. prunifolia* var. *ringo*) that had been pre-cultured in a soil medium for horticulture. Inoculated apple plants were continued to be cultured in the soil for additional 2 weeks. The mycelial expansion is shown by white arrows while inoculation sites are denoted by arrowheads. Levels of the mycelial growth on apple rootstocks are equivalent to virulence levels. These figures are reproduced from Chiba, S., Salaipeth, L., Lin, Y., *et al.*, 2009. A novel bipartite double-stranded RNA mycovirus from the white root rot fungus *Rosellinia necatrix*. Molecular and biological characterization, taxonomic considerations, and potential for biological control. *Journal of Virology* 83, 12801–12812, with permission from the American Society for Microbiology.

C. parasitica contributes to its tolerance to RnMBV1, which is stably maintained in both the wild type and $\Delta dcl2$ genotypes during repeated subculture on media.

There is little information on the vertical transmission of the megabirnavirus in nature. The vertical transmission rate of RnMBV1 was investigated in *C. parasitica*, in which asexual spores can be easily formed, and it was found to be substantially low (<1%) in both the wild type and $\Delta dcl2$ genotypes of *C. parasitica*.

All of the three well-characterized megabirnaviruses, namely RnMBV1 and two unassigned viruses termed *Sclerotinia sclerotiorum* megabirnavirus 1 (SsMBV1) and *Rosellinia necatrix* megabirnavirus 2 (RnMBV2), have bi-segmented dsRNA genomes and are associated with host phenotypic alterations. However, virion transfection of host fungal strains often leads to genome alterations, including genome rearrangements and segment loss. Examination of such RnMBV1 transfectants suggests the dispensability of ORF3- and ORF4-encoded proteins. Even the complete loss of dsRNA2 is tolerated for virus viability, as discussed below.

Taxonomic and Phylogenetic Considerations

The Megabirnaviridae family currently consists of a single genus, *Megabirnavirus*, to which only one species, *Rosellinia necatrix* megabirnavirus 1, is assigned. Based on identity of the deduced amino acid sequence of RdRP, megabirnaviruses are placed in a

Fig. 6 Phylogenetic analysis of megabirnavirus and related, unclassified viruses. Phylogenetic trees were constructed based on the complete deduced amino acid sequences of RdRP (a) and P1 (b). Full name of megabirnavirus and related viruses can be found to [Tables 1 and 2](#). The chrysoviruses (HvV145S: *Helminthosporium victoriae* 145S virus; PcV: *Penicillium chrysogenum* virus; and VdCV: *Vorticillium dahliae* chrysovirus 1) are also included as an outgroup. The sequences obtained from GenBank were aligned using MUSCLE. The evolutionary history was inferred using the Neighbor-Joining method and the evolutionary distances were computed using the Poisson correction method. The percentage of reproducibility of trees in the bootstrap test (1000 replicates) are indicated next to the branches. The whole step was conducted using MEGA7 software.

phylogenetic group distinct from the known dsRNA mycoviruses, such as members of the *Chrysoviridae* and *Totiviridae* families. Although megabirnaviruses are phylogenetically related to these dsRNA virus families, megabirnaviruses possess genome organizations and virion structures that are distinct from these viruses.

Recently, several unclassified mycoviruses that are closely related to a member of the *Megabirnaviridae* family have been discovered (Table 2, Fig. 6). Among them, SsMBV1 and RnMBV2 are most closely related to RnMBV1 and have been characterized in detail. The genome organizations and sizes of these two viruses are very similar to RnMBV1 (Tables 1 and 2, Fig. 7). SsMBV1 and RnMBV2 also have bi-segmented linear dsRNA genomes, which consists of 8.8–8.9 kbp of dsRNA1 and 7.2–7.9 kbp of dsRNA2. Both segments of each virus contain two ORFs, long 5'-UTRs that are more than 1.6 kbp and relatively short 3'-UTR. The signature sequence for translation of RdRP via ribosomal -1 frameshifting is also conserved between RnMBV1, SsMBV1 and RnMBV2. The conservation of 5'-UTR sequence between dsRNA1 and dsRNA2 is stricter in SsMBV1 and RnMBV2 than in RnMBV1.

SsMBV1 was found in an ascomycete fungus, *Sclerotinia sclerotiorum*. Unlike the P3 of RnMBV1 or RnMBV2, the P3 of SsMBV1 contains a conserved papain-like protease coding domain, which is commonly found in positive-strand, single-stranded RNA viruses, hypoviruses. Phylogenetic analysis suggests that this papain-like protease domain in the SsMBV1 genome might have been horizontally transferred from *Cryphonectria hypovirus* 1. SsMBV1 moderately attenuates the growth of *S. sclerotiorum*.

RnMBV2 was isolated from the same host species, *R. necatrix*, as RnMBV1, although the two infected host strains were collected from different prefectures in Japan. RnMBV2 would be classified as a distinct species from RnMBV1, based on phylogenetic distances, identity of amino acid sequence of hypothetical proteins and virulence to the host. Phylogenetic analysis based on the

Fig. 7 Genome organization of megabirnavirus and related, unclassified viruses. Abbreviations of virus names corresponds to viruses listed in Tables 1 and 2. Doubled lines indicate dsRNA. ORF1, ORF2, ORF3 and ORF4 are represented by green, orange, purple and yellow boxes, respectively. The position and sequence of putative slippery heptamer adjacent to the stop codon of ORF1 is indicated with an arrow. The position of papain-like protease domain in ORF3 of SsMBV1 is indicated with a red box.

deduced amino acid sequence of RdRP and CP indicates that RnMBV2 is more closely related to SsMBV1 than to RnMBV1 (Fig. 6). A single infection by RnMBV2 causes no obvious effects on *R. necatrix*, which is in contrast to infection by RnMBV1. However, co-infection by RnMBV2 and a partitivirus, *Rosellinia necatrix* partitivirus 1 (RnPV1), induces apparent growth inhibition of *R. necatrix*, although single-infections involving either virus does not. The enhanced RnPV1 replication likely underlies this synergistic interaction between RnMBV2 and RnPV1.

In addition to SsMBV1 and RnMBV2, several unclassified viruses closely related to megabirnaviruses were found in diverse ascomycetous and basidiomycetous fungi. These include *Fusarium pseudograminearum* megabirnavirus 1 (FpgMBV1), *Pleosporales* megabirnavirus 1 (PmbV1), *Rosellinia necatrix* megabirnavirus 3 (RnMBV3), *Entoleuca* megabirnavirus 1 (EnMBV1), *Rhizoctonia solani* megabirnavirus 1 (RsMBV1) and *Rhizoctonia solani* RNA virus HN008 (RsRV-HN008) (Table 2, Fig. 6). FpgMBV1, PmbV1 and RsRV-HN008 have been detected in single infections of the respective original host fungi, while RnMBV3, EnMBV1 and RsMBV1 have been detected in mixed infections with other viruses by next-generation sequencing-based virome analyses. Thus, only the sequence of dsRNA1 (RnMBV3 and EnMBV1) or the partial sequence of RdRP (RsMBV1) have been reported, and the complete genome organizations of these three viruses remain unknown. The dsRNA1 sequences of FpgMBV1, PmbV1, RnMBV3 and EnMBV1 are similar to that of RnMBV1 in several aspects: (1) dsRNA size (8.8–9.0 kbp), (2) 5'-UTR length (> 1.6 kbp), (3) location of ORF2 (RdRP encoding gene) in -1 reading frame, relative to ORF1 and (4) presence of atypical shifty heptamer (5'-G RAA AAC-3', here R represents A or G) resembling a typical one (5'-A AAA AAC-3') immediately upstream of the stop codon of ORF1 (Fig. 7). The dsRNA2 sequence of FpgMBV1 and PmbV1 (5.1–5.3 kbp) is much shorter than dsRNA2s of RnMBV1, SsMBV1 and RnMBV2 (7.2–8.0 kbp). RsRV-HN008 is distinct from these other megabirna-related viruses; RsRV-HN008 has a monosegmented genome with a short 5'-UTR (39 bp) and two ORFs in the same reading frame (Fig. 7). All of these viruses, including RsRV-HN008, are placed on the same phylogenetic clade based on the identity of the deduced amino acid sequence of CP or P1, as well as RdRP (Fig. 6). Further consideration is required for the cogent classification of these viruses and the setting of criteria for the family *Megabirnaviridae*.

Future Perspectives

Functions of Megabirna-P3 and -P4

It has been confirmed that P3s, but not P4s, of RnMBV1 are expressed in infected fungal tissues; however, elucidation of the functions of P3 and P4 is a future research challenge. Artificial virion transfection of *R. necatrix* by RnMBV1 occasionally leads to the loss of dsRNA2, which simultaneously triggers the emergence of rearranged segments derived from dsRNA1. RnMBV1 mutants lacking dsRNA2 are capable of replicating and packaging, but showed impaired replication and attenuated hypovirulence to fungal hosts in comparison with wild type RnMBV1. Furthermore, dsRNA2-lacking RnMBV1 mutants appear to require rearranged dsRNA1 derivatives, in addition to intact dsRNA1, to stably infect the host fungus. Similarly, SsMBV1 mutants lacking dsRNA2 emerge by transfection of wild type SsMBV1 into *S. sclerotiorum*. SsMBV1 mutants without dsRNA2 also accumulate lower amounts of dsRNA1 compared to wild type. Thus, dsRNA2 of megabirnaviruses seems to be involved in efficient replication, translation and/or stability of dsRNA1. DsRNA2 is also likely to contribute to increased virulence to hosts. It remains to be elucidated whether megabirna-P3 and -P4 or the dsRNA itself plays a role in these contexts.

Glossary

Anastomosis Fusion between hyphal branches allowing for exchange of cytoplasm, ions, and organelles, and the most common means of horizontal transmission of mycoviruses.

Conidia Asexual, non-motile fungal spores.

Haplotype Group of alleles inherited together. In the case of haploid fungi, it constitutes the genetic makeup of the individual.

Non-retroviral endogenous RNA (NERVE) Genetic elements comprised of fragments or complete genomes

derived from non-retroviral RNA viruses found embedded in eukaryotic genomes.

Protoplast A cell that has its cell wall removed, allowing for membrane fusion and permeabilization.

RNA silencing The negative regulation or inhibition of gene expression by non-coding RNA elements. Also called RNA interference (RNAi).

Vegetative incompatibility Genetic differences between fusing vegetative hyphae of fungi that result in unviable heterokaryons and prevent horizontal mycovirus transmission.

The genus *Mitovirus* contains arguably the simplest of all viruses known: an RNA molecule often of less than 3 kb encodes only RNA-dependent RNA polymerase (RdRp) that serves to direct replication of the simple genome. They are called mitoviruses because they reside in mitochondria. In common with several other fungal viruses, mitoviruses have no capsid protein, but rather consist of RNA, likely encapsulated in lipid vesicles together with virally-encoded RNA-dependent RNA polymerase. Mitoviruses are now known to be abundant in fungi – possibly the most common of all fungal viruses – and they are now suspected to be components of the plant virome as well.

Most mitoviruses have been identified through double-stranded (ds) RNA screening of fungal cultures, a commonly used method to screen fungal culture collections for virus presence. Mitovirus dsRNA is usually relatively abundant in infected cultures, consistent with either a dsRNA or positive sense (+) RNA genome. Free + RNA is more abundant in cultures than free negative-sense (−) RNA, consistent with a + RNA mitovirus genome. Phylogenetic relatedness of mitovirus RdRp coding sequences to + RNA viruses rather than − RNA viruses or dsRNA viruses supports their classification as + RNA viruses.

Although they were first characterized in the mid 1990s, relatively little progress has been made on details of their replication and life cycles. This is in large part because of the lack of good infectivity systems. As mitoviruses have no protein-containing particles to deliver infectious nucleic acid and delivery into mitochondria is required to initiate infection, transmission has been accomplished to date only vertically via asexual or sexual spores, or horizontally by hyphal anastomosis. No one yet has developed a robust reverse genetics system – that is, infectious cDNA clones – for any mitovirus. Recent demonstration of mitovirus transmission to marked heterologous species, genera, and families opens the door for deeper examination of host range and phenotypic effects of a single mitovirus in different host backgrounds.

Genome Structure

There is relatively little variation in mitovirus genome size and structure (Fig. 1). The largest mitovirus genome sequenced to date is ~5.0 kb from the basidiomycete *Heterobasidion annosum*; the smallest is ~2.2 kb from the ascomycete *Sclerotinia sclerotiorum*. In

Fig. 1 Genome maps drawn to scale of representative viruses belonging to the genus *Mitovirus* and close relatives. Color-coded regions represent conserved domains including: RdRp; RNA-dependent RNA polymerase (red), MP; movement protein (green), CP; capsid protein (blue), maturation protein (orange), and Lys; lysis protein (purple). Within each genus, there is variability with respect to genome size, RdRp protein size, and number of nucleotides in the non-translated sequences at 5'- and 3' termini. Size ranges of each of these elements within members of each genus are provided.

all cases, a single ORF encodes the RdRp and no other known proteins. A hallmark of fungal mitovirus RNAs is the presence of UGA codons distributed throughout the ORF in varying numbers encoding tryptophan (Try) rather than serving as a terminator of translation (see below). There is no evidence for post-translational processing of mitovirus-encoded proteins and no evidence for the use of additional shorter-than-full-length subgenomic messenger (m) RNAs for mitovirus gene expression. Non-translated sequences at the 5'-end of the RNA vary from 15 to 957 nucleotides; non-translated sequences at the 3'-ends vary from 0 to 1788 nucleotides. Specific host and viral factors required for mitochondrial genome replication and expression have not been investigated in any depth primarily because of the lack of infectious viral cDNA clones that can be manipulated and because of the extreme difficulty associated with manipulating host mitochondrial gene expression.

Accessory RNAs Associated With Mitovirus Infections

In addition to the single, replication-competent RNA of mitoviruses, additional accessory RNA molecules may be found as well. Accessory RNAs that may be associated with RNA virus infections include satellite RNAs, defective or defective-interfering RNAs, or satellite/defective RNA hybrids. Satellite RNAs (S-RNAs) are unrelated by nucleotide sequence to the parent virus, except possibly for 5'- or 3'-terminal nucleotides; defective RNAs (D-RNAs), also called defective genomes, are incomplete deletion mutants derived from the parent RNA; defective-interfering RNAs (DI-RNAs) are defective RNAs that have been demonstrated to interfere with parent virus replication or function. S-RNAs, D-RNAs, and DI-RNAs are all common in fungal RNA virus infections, and all have been identified in mitovirus infections.

A heterogeneous S-RNA population was associated with infection of the mitovirus *Ophiostoma novo-ulmi* mitovirus 3A (OnuMV-3A) in the fungus *Sclerotinia homoeocarpa*, but there was no evidence that the satellite affected accumulation of the parent virus replication. Similarly, D-RNAs were identified in *O. novo-ulmi* strain Ld infected with multiple mitoviruses, but there was no evidence for interference of parent virus replication. In the *Botrytis cinerea* isolate CanBc-1c-78, the mitovirus BcMV-1 was found to be associated with a deletion mutant of the parent viral genome that fits the criteria of a DI-RNA by reducing accumulation of that parent viral RNA. As with other mitovirus investigations, studies on S-RNAs, D-RNAs, and DI-RNAs are hampered by the lack of robust infectivity systems.

Phenotypic Effects of Mitovirus Infection

Many fungal viruses have little measurable effect on fungal colony morphology, growth rate in culture, or virulence, while others may have profound effects. Mitoviruses reflect this spectrum of biological consequences as well, some resulting in symptomless infections but others causing measurable and perhaps severe pathology. The first mitoviruses were identified based on their effects on virulence of the Dutch elm disease fungus in natural settings and colony phenotypes of *O. novo-ulmi* in culture, but that system was particularly difficult to tease apart from the standpoint of satisfying Koch's postulates for individual mitovirus elements because they were numerous, coinfecting, and resulted in different phenotypes in the fungus. The effects of the individual mitoviruses were difficult to quantify in the absence of traditional virology methods such as particle isolation and inoculation to uninfected individuals. In contrast, the first mitovirus identified based on genetic and molecular properties in *C. parasitica* was a single element that had only a slight measurable effect on phenotype, so the challenge was to develop isogenic, virus-free fungal isolates and determine whether the minor changes to growth rate in culture and fungal virulence were caused by the virus itself.

Only recently did Suzuki and colleagues develop a system to separate unambiguously mitovirus effects from host nuclear and mitochondrial backgrounds. Hygromycin-resistant, virus-free isolates were used as recipients in protoplast fusions with virus-containing, hygromycin-sensitive isolates. Following repeated anastomosis and single conidial isolation, resulting mitovirus-containing isolates bearing the nuclear and mitochondrial genotypes of the original recipient isolate were obtained and maintained in continuous culture.

Several mitoviruses appear to have profound effects on fungal phenotype, including virulence on plant hosts. In the ascomycete pathogen of many field crops, *Chalara elegans* (= *Thielaviopsis basicola*), reduced fungal growth, reduced melanin production, and reduced virulence have been associated with mitovirus presence. Furthermore, smaller and fewer mitochondria were associated with mitovirus-bearing isolates compared to their mitovirus-free counterparts. Similarly, a mitovirus from the broad host range plant pathogen *Botrytis cinerea* was shown to have deleterious effects on its fungal host and on the infected mitochondria themselves. In each of these two cases, the mitovirus was not completely eliminated from the fungal host, so conclusions of direct causality of the virus and quantifying disease effects were tempered.

Mixed infection of a single fungal thallus by multiple mitoviruses has been demonstrated in several instances. In *O. novo-ulmi*, single conidial isolates of debilitated, multiply-infected isolates were used to help identify mitoviruses that affected fungal phenotype and those that did not. Multiple mitoviruses have also been shown to infect single isolates of *Sclerotinia* and *Botrytis*. Still unknown is whether multiple mitoviruses infect and replicate together in single mitochondria, or whether instead each mitochondrion within the population of mitochondria in a fungal thallus is infected with a single mitovirus. As noted for other mitovirus infectivity studies, experiments to address this question are challenging.

Fig. 2 Maximum likelihood (ML) phylogenetic tree based on multiple sequence alignment of full-length RNA-dependent RNA polymerase (RdRp) protein sequences from 130 mitoviruses. Sequences were aligned with MUSCLE and implemented in IQ-TREE with model selection parameters. A VT + F + I + G4 model of evolution was selected based on the Akaike information criterion (AIC) and Bayesian information criterion (BIC). Bootstrap support above 60% is displayed above branches, calculated from 2000 ultrafast bootstrap replicates. Major clades are colored to denote the following groups: genus *Levivirus* (yellow), genus *Narnavirus* (red), genus *Ourmiavirus* (gray), genus *Mitovirus* clade B (blue), and genus *Mitovirus* clade A (green). Assembled mitovirus RNA sequences from plants form a monophyletic clade within mitovirus clade A and are denoted by a darker shade of green.

Phylogenetic Relationships

Phylogenetic reconstruction of 130 mitovirus sequences reveal a well-supported monophyletic group containing two major clades; a smaller subset of those isolates is provided in Fig. 2. Clade A contains mitovirus sequences determined from a range of Ascomycete and Basidiomycete fungi as well as all identified plant mitoviruses, which form an independent monophyletic group. Mitovirus clade B is comprised of virus isolates from similar fungi, but no plant mitoviruses. High bootstrap values support the separation of the mitovirus clade from its sister clade containing the narnaviruses and ourmiaviruses.

It is notable that several fungal taxa harbor mitoviruses from both clades A and B, and that individual mitovirus species from a single fungal species are distributed broadly within those clades. These observations suggest that mitoviruses have entered fungal taxa such as *Ophiostoma*, *Sclerotinia*, and *Botrytis* independently multiple times.

Taxonomy and Nomenclature

Under current ICTV taxonomy, the family *Narnaviridae* contains two genera: the genus *Narnavirus* and the genus *Mitovirus*. Continued reassessment of the overall taxonomy of these and related viruses is needed, as members of the genus *Narnavirus* are more closely related to the plant-infecting viruses in the genus *Ourmiavirus*, in the recently approved family *Botourmiaviridae*, than they are to the mitoviruses. Thus, it is likely that the mitoviruses and narnaviruses will eventually be separated into different families.

The genus *Mitovirus* currently contains all members discussed in this article. At this time, other than the association with different host taxa, there are no solid biological criteria on which to subdivide the taxon. Based on the strong evidence for at least

two distinct mitovirus clades, one of which includes all known presumed plant-associated mitoviruses and related sequences, it might be useful to subdivide this broad taxon into smaller taxa. As the numbers of characterized mitoviruses and putative mitovirus sequences accumulates, it is expected that such a taxonomic proposal would soon be entertained by the ICTV.

Transmission

Mitovirus transmission is not fundamentally unlike transmission of other fungal viruses, but their mitochondrial localization leads to some important differences compared to cytoplasmic viruses. Like other fungal viruses, mitoviruses depend on hyphal anastomosis for horizontal transmission. As such, vegetative incompatibility (VIC) genes and the associated VIC phenotype play a fundamental role in transmission from one fungal thallus to another in natural settings. Mitoviruses are efficiently transmitted upon anastomosis of vegetatively compatible isolates in culture, but details of transmission are only recently coming to light. Considering the mechanism of transmission as it pertains to the mitochondria themselves, two basic possibilities present themselves: mitovirus-containing mitochondria from an infected isolate could enter an uninfected isolate after hyphal anastomosis and then fuse with virus-free mitochondria in the previously uninfected isolate, resulting in delivery of virus by mitochondrial fusion; or the virus-containing mitochondria could enter the uninfected strain and simply take over, eventually replacing the population of uninfected mitochondria with infected ones. In the former model, the resulting mitochondrial haplotype of the newly infected strain would either be the same as it was previously, or would be a hybrid of the two mitochondrial haplotypes; in the latter model, the mitochondrial haplotype of the newly infected strain would be that of the infecting strain. Evidence to date strongly supports the first model: incoming mitochondria deliver virus to resident mitochondria and do not themselves replace the resident population. This has recently allowed for mitovirus transmission among different species of the same genus, among genera within a family, and even across family lines. These transmission experiments have also shown that a mitovirus from one fungal host species may or may not be stable in a new host. More such experiments are needed to better understand factors that regulate mitovirus/host stability.

Vertical transmission of mitoviruses occurs both via sexual and asexual spores. Most mitoviruses have been characterized in ascomycetes, and their transmission has been more thoroughly characterized in those taxa. Transmission through asexual spores such as conidia in ascomycetes is often very efficient, at or near 100% in single conidial isolates derived from an infected isolate. Experimental transmission through sexual ascospores in ascomycetes has been shown to follow a somewhat predictable pattern. In *C. parasitica*, there are two mating types, and mitochondria have been shown to be inherited maternally: all mitochondria in ascospore progeny are derived from the female parent in sexual crosses. This pattern is common, but not universal in fungi. The *C. parasitica* mitovirus CpMV1-NB631 was shown to be transmitted to ~50% of ascospores derived from matings in which the female isolate was infected with CpMV1-NB631, but no transmission occurred when the male isolate in the matings was the infected partner. While that general pattern of virus inheritance follows the pattern predicted from mitochondrial inheritance, it is unclear why only approximately 50% rather than 100% of progeny in these experiments were infected.

Engineering Mitoviruses for Infectivity

Reverse genetics can be effected for most positive strand RNA viruses through the use of infectious cDNA clones. Usually this is a fairly straightforward process: a full-length cDNA clone of the viral RNA is produced in a manner allowing for in vitro transcription of positive-sense RNA representing a replica of the viral RNA itself. The transcript is infectious when introduced into cells. The cDNA clones can then be manipulated through traditional molecular methods to examine functions of specific sequences. To date, no robust reverse genetics system has been reported for mitoviruses. The fundamental problem in developing a true reverse genetics system is delivery of viral-length RNA to mitochondria to initiate the infection process. It is difficult to know how many attempts at such infections have been made – we know of several – but none have yet been reported as successful.

Another approach to examining mitovirus replication involves attempting replication and expression not in mitochondria but in the cytosol, as with most other positive-sense RNA viruses. For mitoviruses, this involves mutating any of the UGA codons to UGG, thereby allowing them to direct cytoplasmic incorporation of the amino acid tryptophan (Try) rather than translation termination. This approach would effectively turn a mitovirus into a narnavirus, which has the same fundamentally simple genome structure, encoding only RdRp, but is naturally localized to cytoplasm rather than mitochondria. Limited success in this approach has been reported, but we are unaware of peer-reviewed journal articles summarizing such studies. Such experiments are of interest from the standpoint of basic virology and examination of factors differentiating narnaviruses and mitoviruses, but they are not replacements for studies examining mitovirus RNA replication in mitochondria.

Host Defense

Within fungi, a primary host defense mechanism against virus attack is thought to be vegetative incompatibility systems, which limit intraspecific hyphal fusion and accordingly limit horizontal virus transmission. This barrier is well-understood in some fungi, including *C. parasitica*, and has been demonstrated to restrict mitovirus transmission experimentally in that fungus and several other fungi. Presumably it functions in nature in fungi with VIC systems as well.

Active, nucleic acid-based antiviral defense systems in plants and fungi are similar to each other, but differ in details and complexity. Both plants and fungi have RNA silencing-based defense systems. Viral suppressors of silencing encoded by related plant and fungal viruses, including the fungal-infecting members of the family *Hypoviridae* and the plant-infecting *Potyviridae*, have been characterized in detail, and the fungal virus hypovirus silencing suppressor, p29, has been shown to function when expressed in plants. There is currently no evidence that mitoviruses encode suppressors of RNA silencing, and comparison of CpMV1 accumulation among various RNA silencing-deficient and competent strains indicated that the virus was unaffected by RNA silencing. CpMV1 did not induce expression of either the dicer-like protein DCL2 or the Argonaut-like protein AGL2, the two RNAi-associated proteins that are known to be components of the RNA virus defense response pathway in fungi. Furthermore, there was no difference in susceptibility of these strains compared to the wild-type strain, as measured by replication level of CpMV1 in fungal strains deleted in the *dcl2* or *agl2* genes. Studying the interactions between fungal – or plant – RNA defense systems and mitoviruses will help answer important fundamental questions about mitovirus biology.

Codon Usage and Implications for Mitovirus Biology and Evolution

Mitoviruses were initially described as mitochondrial elements based on their biology in the Dutch elm disease fungal system, *Ophiostoma novo-ulmi*, and their molecular, genetic, and subcellular properties in the chestnut blight system, *Cryphonectria parasitica*. Although, few comprehensive studies have been done to date in the many mitovirus systems described at the primary sequence level, deep sequencing and subsequent mining of genomic and transcriptomic data have resulted in important advances in our understanding of the biology and evolutionary history of mitoviruses. One of the hallmarks of mitovirus genome structure is their use of the mitochondrial genetic code for translation of their only gene product, the viral RdRp. The observation in the *C. parasitica* mitovirus CpMV1-NB631 that the genome contains numerous UGA codons in an otherwise open reading frame (ORF) encoding a putative RdRp led to the hypothesis that the element is obligately mitochondrial. UGA is a termination codon in the cytosol but encodes tryptophan in most fungal mitochondria, and therefore this CpMV1-NB631 element was predicted to encode a functional RdRp in mitochondria, but have no capacity for translation in the cytosol. As mitovirus sequences accumulated, the universal presence of UGA codons in predicted RdRp ORFs became evident as a general property of these elements.

The accumulation in databases of many mitovirus sequences allowed for systematic analysis of Try-encoding UGA vs. UGG codons in the context of fungal host UGA vs. UGG codon use. These analyses showed that mitovirus UGA codon use mirrored that of the host fungus: that is, fungal taxa that rarely used UGA to encode Try tended to host mitoviruses with few UGA codons.

Origin and Evolution

The phylogenetic tree of plant and fungal mitovirus sequences does not exclude the possibility that fungal mitoviruses derive from their plant counterparts. However, the likely ancient origin of eukaryotic mitoviruses, coupled with the earlier appearance on earth of fungi rather than plants argues for fungi as the earlier mitovirus host. Possible scenarios to envision include entry of a plant mitovirus into a closely associated sympatric fungus, such as an endophyte or mycorrhizal fungus, and subsequent expansion of fungal mitovirus host range and adaptation to fungal mitochondrial codon preferences – i.e., progressive gain of UGA codons within coding sequences – following heterologous fungal anastomosis events and associated mitochondrial fusion events. It is also easy to envision this scenario moving in the other direction: that a fungal mitovirus devoid of UGA codons within the coding sequence similarly entered a plant mitochondrion, took up residence, and expanded from there into other plants.

Perhaps more than other viruses, the extreme simplicity of mitovirus genomes raises questions about how close they are to progenitors of RNA viruses. Recent deep and comprehensive phylogenetic analysis supports the idea that mitoviruses are ancient in origin, with the intriguing possibility that progenitors of contemporary mitoviruses entered the eukaryotic lineage along with the bacterial progenitors of the mitochondrial endosymbiont, possibly by the loss of a capsid protein gene from a progenitor bacterial levivirus. Evolution of mitoviruses within fungi would then parallel evolution of fungal (and plant) mitochondria. Further downstream evolution of viruses in the lineage represented by mitoviruses would presumably involve escape from mitochondria and then either (1) adaptation to a similarly cell-bound but non-mitochondrial, cytosolic lifestyle in the case of narnaviruses and possibly fungal botourmiaviruses, or (2) acquisition of simple capsid protein and movement protein genes and escape from the cell in the case of plant ourmiaviruses.

Plant Mitoviruses

Signature sequences of mitoviruses were among the first non-retroviral endogenous RNA (NERVE) sequences identified in plants, described initially in the late 1990s. Mitovirus sequences have been identified in both mitochondrial and nuclear DNA genomes of plants. Their initial entry and presumably subsequent integration into plant genomes appears to have been an ancient event, possibly dating from the early evolution of clubmosses nearly a half billion years ago. The extent to which mitoviruses have been active members of the plant virome remains a matter of active investigation that will be explored further as broader and deeper genomic coverage of plant phyla becomes available. Some studies suggest that mitoviruses may have entered into plant lineages

multiple times, possibly being lost from a given lineage and then regained through subsequent mitochondrial exchange. Recent evidence based on mining of transcriptome data strongly suggests that mitoviruses are active, contemporary residents of plants and that they form a monophyletic cluster embedded within one of the two major clades of fungal mitovirus elements (see Fig. 2). Furthermore, analysis of plant mitovirus-related NERVE sequences also supports the finding that these elements form a monophyletic group that clusters with the putative contemporary plant mitoviruses discovered from transcriptome data. Unlike fungal mitochondria, UGA codons in plant mitochondria encode a translational stop codon rather than tryptophan; thus, putative plant mitoviruses would not be expected to contain any UGA codons in ORFs, and this is indeed the case.

As mitoviruses are now understood to be a component of the plant virome, we anticipate that other studies will investigate their relative importance in plants. A key question is whether they are cryptic in plants or whether they have a measurable and significant effect on plant development and biology. An interesting finding from associative plant transcriptome studies suggested higher mitovirus expression levels in flowers than other tissues, but these studies were not directed toward asking questions about mitovirus biology. Experimental studies with isogenic plants, similar to those that have been performed in fungi, will help address the possibility. Many of the same types of studies that have been performed in fungal systems are possible in plant systems, and many of the same specific questions will be addressed, for example: is there a measurable effect on plant phenotype; can horizontal transmission be demonstrated and what are mechanistic details; how do RNA defense systems impact plant mitoviruses?

While genome and transcriptome data mining are very valuable tools for mitovirus discovery and analysis, examination of archival dsRNA studies that were performed for discovery of unknown viruses in plants may also be a useful approach. As it is with fungi, most plant viruses contain RNA genomes; in the case of plants, a preponderance of viruses contain positive-sense RNA genomes, and thus replicative form dsRNA accumulates to visually detectable levels in most. Initial discovery of mitoviruses in fungi, and subsequent discovery of most other fungal mitoviruses, has come through screening of samples from culture collections for dsRNA presence. Mitovirus-infected plants might be expected usually to contain a single signature genome-size dsRNA of ~2.5–3 kb, identifiable in archival and published gel photographs, but evidence to date suggests that plant mitovirus dsRNA accumulation is minimal, so such data mining might not lead to further plant mitovirus discovery.

This is an update of B.I. Hillman, Mycoreoviruses, In Encyclopedia of Virology (Third Edition), edited by Brian W.J. Mahy and Marc H.V. Van Regenmortel, Elsevier Ltd., 2008, doi:10.1016/B978-012374410-4.00569-0.

Glossary

Anastomosis Fusion between hyphal branches allowing for exchange of cytoplasm, ions, and organelles, and the most common means of horizontal transmission of mycoviruses.

Ascospores Sexual spores of an ascomycete.

Conidia Asexual, non-motile fungal spores.

Haplotype Group of alleles inherited together. In the case of haploid fungi, it constitutes the genetic makeup of the individual.

Protoplast A cell that has its cell wall removed, allowing for membrane fusion.

Reassortment Exchange of genome segments resulting from co-infection of two or more strains of a multi-segmented virus such as a reovirus.

RNA silencing The negative regulation or inhibition of gene expression by non-coding RNA elements. Also called RNA interference (RNAi).

Vegetative incompatibility Genetic differences between fusing vegetative hyphae of fungi that result in unviable heterokaryons and prevent horizontal mycovirus transmission.

The 9th Report of the International Committee for the Taxonomy of Viruses (ICTV) lists 15 genera of viruses in the family *Reoviridae* divided into two subfamilies, *Sedoreovirinae* and *Spinareovirinae*, that infect mammals, invertebrates, plants, protists, and fungi. Members of many of the reovirus genera in the 9th Report replicate in organisms representing more than one kingdom or phylum: for example, all plant reoviruses replicate in and persistently infect their insect vectors, and similarly many of the mammalian reoviruses replicate in their invertebrate vectors.

The Genus *Mycoreovirus* comprises three fungus-infecting reovirus species, *Mycoreovirus 1*, *Mycoreovirus 2*, and *Mycoreovirus 3*. The exemplar strains of the first two species, mycoreovirus 1 (MyRV1) and MyRV2 were isolated from the filamentous ascomycete fungus *Cryphonectria parasitica*, and that of the last species is from the soilborne fungus *Rosellinia necatrix*, also an ascomycete but representing a different fungal order. A fourth proposed species of the genus infecting the fungal plant pathogen *Sclerotinia sclerotiorum* has been described (here designated MyRV4). Another recently described fungal reovirus, also infecting *S. sclerotiorum*, falls phylogenetically outside of the established genus *Mycoreovirus*. That virus, *Sclerotinia sclerotiorum* reovirus 1 (SsReV1), will nevertheless be discussed in this article.

Mycoreoviruses often cause disease in their infected hosts, resulting in greatly reduced virulence, reduced growth in culture, reduced laccase accumulation, and reduced sporulation relative to wild-type, virus-free cultures of the same genetic background (Fig. 1). The mycoreoviruses are most closely related to members of the genus *Coltivirus* of tick-borne reoviruses (Fig. 2). Both Colorado tick fever virus (CTFV) and the closely related Eyach virus (EyaV) cause disease in mammals, and both viruses replicate in their arthropod vectors as well as in their mammalian hosts. A recently characterized coltivirus from bats was also found to replicate in mammalian cells. The coltiviruses are not well understood at the molecular level and so have shed only a little light on the study of mycoreoviruses. Coltiviruses are more closely related to the genus *Orthoreovirus*, which includes the common human pathogen mammalian reovirus (MRV), than to members of the other two genera of the family *Reoviridae* (*Orbivirus* and *Rotavirus*) that have been well studied at the structural and molecular levels.

Filamentous fungi are valuable subjects for investigation of eukaryotic viruses. This has been especially true for ascomycetes, which usually are haploid throughout their vegetative phases and thus readily amenable to tools of classical genetics and to relatively simple gene knockout and knockdown experiments. The plant pathogenic ascomycete fungi *Cryphonectria parasitica*, *Rosellinia necatrix*, and *S. sclerotiorum* have all been exceptional hosts for examination of fungal viruses: they cause important plant disease, are very stable in culture, showing a consistent morphology upon continued maintenance and subculture, are easily transformed and transfected, and can be examined through classical genetics. Because of their historical importance as plant pathogens and the potential for their control using natural or genetically engineered viruses, a large array of diverse viruses that cause stable morphological changes and/or changes in virulence of their fungal hosts have been identified and characterized in these fungi.

Structure-Function Relationships

Relatively little is known of the details of mycoreovirus structure, but all indications from electron micrographs of negatively stained virus particles and genome sequence analysis are consistent with the *Spinareovirinae* subfamily, best studied in the orthoreoviruses. The orthoreoviruses, typified by mammalian orthoreovirus (MRV), are distinguished from the members of the subfamily *Sedoreovirinae* such as orbiviruses and rotaviruses in that they have identifiable pentameric turrets on top of each

Fig. 1 Morphologies of isogenic *Cryphonectria parasitica* colonies infected with three mycoviruses. (a) Uninfected colony, strain EP155; (b) Strain EP155 infected with hypovirus CHV1/EP713; (c) Strain EP155 infected with mycoreovirus MyRV1/Cp9B21; (d) Strain EP155 infected with mycoreovirus MyRV2/CpC18.

Fig. 2 Neighbor-joining (NJ) phylogeny of members of the family *Reoviridae* based on a multiple sequence alignment of full-length RdRp protein sequences. Amino acid sequences were aligned using MUSCLE. Phylogenetic tree was reconstructed using MEGA version 7 under the Poisson model with 1000 bootstrap replicates. Numbers above branches represent bootstrap support above 70%. Taxa that do not belong to a named clade represent unclassified viruses within Reoviridae. Taxa are colored according to host type: fungus (orange), mammal (red), invertebrate (gray), plant (green), and fish (blue).

fivefold axis of the core particle, and these have been demonstrated to be involved in capping of nascent mRNA. The protein that was experimentally demonstrated to be the mycoreovirus guanylyltransferase is homologous to turret proteins of orthoreoviruses that have the same function, supporting the grouping of mycoreoviruses within the *Spinareovirinae* subfamily of the family *Reoviridae*.

Movement of fungal viruses within the mycelium and during horizontal or vertical virus transmission is also relatively poorly understood. Viruses that have been investigated are generally found in hyphal tip cells and move with the growing mycelium; however, location of mycoreoviruses within the mycelium has not been investigated. The steps in the infection process of the mammalian orthoreovirus have been investigated in considerable detail. Virus entry into cells via vesicles occurs by receptor-mediated endocytosis, whereupon the m1 protein, which is myristoylated at its N-terminus and inserted into the inner membrane of the vesicle, cleaves autocatalytically, resulting in pore formation in the vesicle membrane and subsequent virus release into the cytoplasm. Both of the *C. parasitica* mycoreoviruses have homologs of the orthoreovirus m1 protein, with strong myristoylation signals at the amino termini of the corresponding proteins and putative sites for autocatalytic cleavage. This suggests that a similar mechanism of egress from vesicles is a component of the infection cycle of these reoviruses. Interestingly, although the *R. necatrix* mycoreovirus, MyRV3/RnW370, contains a homolog of the m1 protein, it does not contain a glycine residue at the penultimate position of the N-terminus of this deduced protein, and based on its sequence it has a very low predicted probability of myristoylation. It does, however, contain the N/P putative cleavage motif at a similar position and in a similar environment as those in the other viruses.

It is relatively easy to cure *C. parasitica*, *R. necatrix*, and *S. sclerotiorum* from their associated mycoreoviruses. In *C. parasitica*, single asexual spores are usually virus free, and in *R. necatrix*, cultures initiated from excised hyphal tips (the terminal 2–8 cells) are also virus free. In *S. sclerotiorum*, colonies regenerated from individual protoplasts derived from virus-infected cultures may be virus-free. These are in contrast, for example to cultures infected with the well-studied hypovirus of *C. parasitica*, *Cryphonectria hypovirus 1* (CHV1), in which most or sometimes all conidia contain virus and virus infected cultures cannot easily be cured by hyphal tip isolation. It is likely the case that details of mycoreovirus movement within the mycelium as well as horizontal and vertical transmission are quite different from those properties of hypoviruses, which have no capsid protein, are more closely related to positive-sense single-stranded RNA viruses such as plant potyviruses and animal picornaviruses, and whose replication is associated with the fungal trans-Golgi network.

Taxonomy and Nomenclature

Naming of fungal viruses is often problematic because infectivity studies are very difficult with fungal viruses and have not been done with most. In nature, fungal viruses do not exit completely from an infected isolate and enter an uninfected one exogenously. Instead, they move from one isolate to another only after the hyphae of the two isolates have fused (anastomosed), in which case the contents of one or usually more cells from the infected and uninfected isolate are mixed. Mixed infections are common and symptomless infections are the norm for fungal viruses. For these reasons, fungal virus names usually contain reference not only to the host genus and species, but to the host strain of origin as well. The genus name *Mycoreovirus* was a natural one to use because it is descriptive. For the sake of simplicity and consistency with other viral nomenclature, species are numbered progressively as they are described. The fungal species and isolate in which a particular virus was identified is provided after the species number.

In this system, the first mycoreovirus species described was designated *Mycoreovirus 1*. The only isolate of this virus species identified to date was from *C. parasitica* strain 9B21, so the virus is designated mycoreovirus 1/Cp9B21 or MyRV1/Cp9B21. The reason that MyRV2 represents a separate virus species even though the two were isolated from the same fungal species and only a few miles away is because it shares much less sequence similarity at both the nucleotide and amino acid levels (<50%) than would be expected for two viruses in a single species. Surprisingly, both of these species are monotypic: these two virus isolates, each representing a different species, are the only two mycoreoviruses isolated to date from *C. parasitica*, even though thousands of isolates infected with members of the family *Hypoviridae* have been identified worldwide. In contrast, mycoreoviruses from dozens of isolates of *R. necatrix* from different parts of Japan have been isolated, but all are closely related to each other, indicating that they represent strains of a single virus species, *Mycoreovirus 3*.

The two distinct reoviruses characterized from the phytopathogenic ascomycete *S. sclerotiorum* are not closely related to each other and most likely represent independent introductions to the fungus by viruses evolved elsewhere. One of the viruses falls within the same clade as the other mycoreoviruses and for consistency here and in keeping with the ICTV species names is designated *Mycoreovirus 4*. In fact, the predicted amino acid sequences of the 12 MyRV4 segments share an average of ~80% identity with homologous segments of MyRV3, and terminal nucleotide sequences of MyRV3 and 4 are identical, indicating that they are recently diverged species.

The other *Sclerotinia* reovirus, which has been designated *Sclerotinia sclerotiorum* reovirus 1 (SsReV1), falls well outside of the clade containing the four viruses within the genus *Mycoreovirus*; in fact, SsReV1 is more distant from members of the genus *Mycoreovirus* than it is to members of the genus *Coltivirus* (Fig. 2). SsReV1 shows some properties distinct from those other viruses, discussed below, and has been proposed to constitute the basis for a new genus within the family *Reoviridae* based on these phylogenetic relationships and predicted coding for proteins not found in the four species of the genus *Mycoreovirus*.

Fig. 3 Diagram illustrating the genome segments of mycoreovirus1/Cp9B21 drawn to scale with respect to size, open reading frame (ORF), and 5' and 3' untranslated regions (UTR). Segment size, ORF in number of amino acids and predicted protein product size, and putative protein function assigned to each genome segment are shown.

Genome Structures, Organizations, and Relationships

Three members of the genus *Mycoreovirus* examined to date appear to have 11 segments of dsRNA that are required for infection. Isolates of one of the viruses, MyRV3, have been found to have either 12 or 11 segments (see below). Whether any of the 12 dsRNA segments of the closely related virus MyRV4 is dispensable for stable infection of *S. sclerotiorum* is unknown. There is significant sequence similarity among the larger segments of the four mycoreovirus species and between homologous segments of the mycoreoviruses and their closest relatives, the coltiviruses, but this similarity becomes less apparent in the middle segments and is not apparent at all in the smallest segments. This feature is common with other members of the family *Reoviridae*, in which the more distant relationships are generally revealed in only the large segments. Each of the 11 required segments of mycoreoviruses appears to contain a single open reading frame (Fig. 3).

Segments 1–5 of the mycoreoviruses are homologous to segments 1–5 of the coltiviruses (segments 4 and 5 of MyRV2 are transposed relative to the others). Based largely on similarity with other reoviruses, their predicted functions are: S1: RNA-dependent RNA polymerase (core protein); S2: dsRNA-binding; putative methyltransferase (core protein); S3: Guanylyltransferase (turret protein); S4: Myristoylated membrane penetration protein (outer capsid); S5: Cytoskeleton-interacting (core). Segment 6 of the mycoreoviruses is predicted to encode a nucleic acid binding core protein and is homologous to segment 10 of the two coltiviruses. Segment 7 of MyRV1 encodes a proline rich protein with similarity to several viral and nonviral proline-rich domains. Homologies among the smaller mycoreovirus proteins (from S8–11 or 12) and other reovirus deduced proteins, including those of coltiviruses, are unknown.

One of the indications of close relationship among reoviruses is conserved terminal sequences. This also is a good indication of whether or not pseudorecombinants can be generated by co-infection with two related viruses. In the case of the mycoreoviruses, the MyRV1, MyRV2, and MyRV3 have different conserved terminal sequences, consistent with their taxonomic separation. Terminal sequences of MyRV3 and MyRV4 are identical, supporting their close relationship.

Mycoreovirus 1

Although MyRV1 was not the first of the two *C. parasitica* reoviruses identified, fungal cultures infected with this virus proved to be more stable and easily studied than those infected with MyRV2 (see below), so early molecular investigations have focused on this virus. When grown on solid media in Petri dishes (e.g., a defined complete medium or potato dextrose agar (PDA)), MyRV1-infected colonies are deep orange in color and have little aerial hyphae compared to their uninfected counterparts. As with other *C. parasitica* viruses, the phenotype of the infected culture has very little to do with the host isolate but is determined almost entirely by the virus.

Fungal isolates infected with MyRV1 are much less virulent than uninfected isolates, and are among the most debilitated of any virus-infected *C. parasitica* cultures studied to date. Although the virus accumulates to reasonably high concentrations in infected colonies, it is transmitted very poorly through conidia, at rates of only 2%–5%. This may account in part for the rarity of the virus in nature.

Expression of MyRV1 Gene Products

Functional analysis of the MyRV1 genome was initiated by cloning the 11 individual segments into a baculovirus expression vector and expressing them in insect cells. All 11 segments were expressed, resulting in 11 identifiable protein products on polyacrylamide gels. Only one of the proteins, the segment 3 product, has been studied functionally. This protein was found to be active in autoguanylation assays, confirming it as the viral guanylyltransferase. Deletion and site-directed mutational analysis determined that the amino acid sequence EPAGYHPRPSIVVPHYFVFR constituted the catalytically active site of the MyRV-1/Cp9B21 guanylyltransferase. The Hx8H motif was identified as absolutely conserved in all three members of the genus *Mycoreovirus*, as well as in the structurally related genera *Coltivirus*, *Orthoreovirus*, *Aquareovirus*, *Cypovirus*, *Dinovernavirus*, *Oryzavirus*, and *Fijivirus*. In all of the above genera in which the guanylyltransferase has been identified functionally, the Hx8H motif has been found within the sequence. The core consensus sequence for the guanylyltransferase within this group of genera was a/vxxHxxxxxxxxHhyf/lvf, with only the H residues being absolutely conserved.

Mycoreovirus 2

The first virus that was tentatively identified as a mycoreovirus was MyRV2. Like many of the virus infected *C. parasitica* cultures, the one that was found to contain this virus was isolated from a canker on an American chestnut tree. The circumstances of the discovery were somewhat unusual in that only one of 36 fungal isolates from that particular canker was virus infected; the rest were virus free. Although it is not unusual to find mixed fungal infections within a canker or to isolate virus-containing and virus-free cultures from one canker, the ratio of 1/36 is extraordinary. The phenotype of the infected culture, designated C-18 (the 18th isolate from canker C on that particular tree) was distinct from the phenotype of MyRV-1/Cp9B21-infected cultures described above in that it was light brown in color and had more aerial mycelium (Fig. 1). MyRV1 and MyRV2 have very similar, dramatic negative effects on fungal virulence. The recent finding that the original C-18 culture is co-infected with the unrelated virus CHV4 and that CHV4 helps stabilize MyRV2 in *C. parasitica*, likely as a result of suppression of RNA silencing, adds interesting complexity to understanding of mycoreoviruses.

A major difference between the two *C. parasitica* mycoreoviruses is their stability and transmissibility. MyRV2 is easily lost upon subculture of the fungus, while this has never been observed with MyRV1. Furthermore, MyRV2/CpC18 is extremely difficult to transmit from an infected isolate to an isogenic uninfected isolate by hyphal anastomosis, a property that is not seen with other *C. parasitica* viruses. It is presumed that these properties are related, but their reasons have not been fully elucidated. Both MyRV1 and MyRV2 have been transmitted to uninfected fungal isolates by inoculating *C. parasitica* protoplasts with purified virus particle preparations and allowing the protoplast to regenerate cell walls, form a hyphal network, and grow into a single colony. The ability to infect protoplasts efficiently using purified virus particle preparations is an interesting and useful feature of *C. parasitica* reoviruses and has been used for a number of other viruses recently. This has allowed for making isogenic virus-infected and virus-free isolates, starting with different genotypes of *C. parasitica* regardless of vegetative incompatibility group and for experimental transmission of mycoreoviruses to different species, genera, and families of fungi.

Mycoreovirus 3

White rot is a root disease of fruit trees that can be limiting to production. Control of the fungus that causes the disease, *Rosellinia necatrix*, by chemical means is difficult and not economically feasible. Plant pathologists in Japan, where the disease is particularly severe, have sought to use virus-infected strains to control the disease, leading to the identification of several viruses. This plant/fungus interaction represents an interesting contrast to the chestnut/*C. parasitica* interaction. As a root disease, there are challenges and opportunities for biological control of a fungal pathogen with viruses that do not apply to aerial diseases. One of the viruses under investigation for biocontrol of *R. necatrix* is the mycoreovirus MyRV3, which causes reduced virulence of the fungus. Unlike the monotypic *C. parasitica* reoviruses, different strains of MyRV3 have been isolated from a variety of *R. necatrix* strains from around Japan.

Of the *R. necatrix* reoviruses, the virus isolate that has been most thoroughly characterized is MyRV3/RnW370. In surprising contrast to the *C. parasitica* viruses, MyRV3/RnW370 was found to contain 12 rather than 11 segments. However, the presence of 12 segments is not a necessary feature of MyRV3: *R. necatrix* isolates derived from subculture of original virus-infected isolates may have either 12 or 11 segments. Experiments to investigate virus composition and transmission have been performed on hyphal tip cultures from infected *R. necatrix* isolates, resulting in demonstration that these viruses behave like the *C. parasitica* mycoreoviruses.

When only 11 segments are present in MyRV3 subculture isolates, segment 8 is the one that is absent from the full complement. With most reoviruses, sequence conservation among species and genera is evident in the larger segments, but much less so in the smaller segments, and this is true in the mycoreoviruses and related genera. Consistent with this general trend, sequence comparison between the 12 segments of MyRV3 and the 12 segments of the two coltiviruses has suggested nothing about possible function of the apparently dispensable segment 8.

It is intriguing to think that perhaps MyRV3 segment 8 is vestigial for reoviruses in fungi and is required only in another host, past, or present. This would be similar to the leafhopper-transmitted phytoreovirus, wound tumor virus (WTV), in which deletion

mutations in any of three segments may be found upon successive serial, insect-free virus passage, or long-term virus maintenance in plants, whereupon resulting mutant viruses become defective in their transmission properties and incapable of replicating in their leafhopper vectors. An apparent major difference between MyRV3 and WTV is that in MyRV3 there is no evidence for terminal remnants of segment 8 in deletion mutant strains; it appears to be either present or entirely absent. In the well-characterized mutants of WTV, the deleted segments were not completely absent; rather, shorter mutant segments containing the two termini and varying amounts of adjacent sequence remain, ensuring that a total of 12 segments remain. Whether this represents a difference between the dsRNA segment sorting and packaging mechanisms of phytoreoviruses and mycoreoviruses is not known. In this line of inquiry, the close association of fungi with mites in natural settings may be significant to the evolutionary biology of mycoreoviruses: it may be no coincidence that their closest relatives are the tick-borne coltivirus, with ticks and mites both in the arachnid subclass Acari. Unfortunately, mites are very difficult experimental subjects and cell cultures are not currently available. Furthermore, much less is known about coltivirus gene function than is known about many of the other members of the family *Reoviridae* that are pathogenic to humans, making it more difficult to pursue this line of research from a strictly bioinformatics standpoint.

Sclerotinia Sclerotiorum Reoviruses

Mycoreovirus 4

MyRV4 from *S. sclerotiorum* is most closely related to MyRV3 from *R. necatrix*, and even though the two were identified in fungi representing distinct classes of ascomycetes, they are more similar to each other than are MyRV1 and MyRV2 to each other, even though the latter two were both isolated from *C. parasitica* only a few miles apart from each other. MyRV4 infection of *S. sclerotiorum* reduces virulence of the fungus on its plant hosts and also suppresses host non-self recognition, or vegetative incompatibility, in the fungus. In doing so, MyRV4 appears to enhance its own spread in nature by lowering the existing barriers to spread within heterogeneous field populations. Like its closest relative MyRV3, MyRV4 contains 12 segments of dsRNA. Each of the 12 segments of MyRV4 has a homologous MyRV3 segment, so these viruses will be good candidates for comparative genomics and for potential coinfection studies. Unlike MyRV3, in which stable virus isolates containing only 11 dsRNA segments (i.e., lacking segment 8) have been identified, no MyRV4 isolates containing only 11 dsRNA segments have yet been reported. Segment 8 of MyRV4 shares 77% nucleotide identity with MyRV3, so it would not be surprising to find similar MyRV4 isolates lacking this segment.

MyRV4 is also associated with distinct alterations to fungal colony morphology in culture, and to alterations in fungal gene expression. Suppression of *het* gene expression, the genes associated with heterokaryon, or vegetative compatibility explains the observed suppression of vegetative incompatibility and increased virus transmission among diverse fungal strains. Reduction in expression of reactive oxygen species (ROS) genes by MyRV4 infection also likely contributes to the same phenotype.

Sclerotinia Sclerotiorum Reovirus 1

In addition to its greater phylogenetic distance from the four members of the genus *Mycoreovirus*, the other *Sclerotinia* reovirus, SsReV1, differs from those in that it causes no identified morphological or phenotypic change to the host fungus. SsReV1 was originally isolated from a hypovirulent strain of *S. sclerotiorum*, but infection with purified virus demonstrated that it was not the cause of the hypovirulent phenotype. A notable feature of the SsReV1 genome is the presence of two domains that were identified in several other viruses and eukaryotes, but not in mycoreoviruses. One of the domains, a dsRNA binding motif, was found especially in DNA viruses and also in cellular host genomes. The other domain, the Reo σ C capsid domain, was more commonly found in other reoviruses but also in DNA-containing viruses. A possible new reovirus genus encompassing SsReV1 has not yet been described.

Effects of Mycoreoviruses on Fungal Gene Expression

Considerable information has been amassed on the impact of CHV1, a positive-sense RNA virus, on its fungal host (see *Hypoviridae*). In contrast, studying the mechanisms of mycoreovirus infection on fungi is in its infancy. The first study addressing these questions was done by microarray analysis using mRNA isolated from isogenic fungal isolates of *C. parasitica* infected with either MyRV1 or MyRV2, and comparing results to the same fungal strain that was uninfected or infected with either of two different CHV1 strains, and with fungal mutants defective in virulence characteristics. To date, these experiments have been performed only on EST-based arrays representing ~20% of the total *C. parasitica* gene complement. Overall, there was consistency in the effects of the two *C. parasitica* mycoreoviruses on host gene expression: MyRV1 infection resulted in differential expression of 6.5% of the genes on the array, whereas MyRV2 infection affected expression of 5.8% of those genes. As might be expected based on their phenotypes, similar but distinct suites of genes were up- or downregulated in isogenic fungal isolates infected with the two reoviruses. Approximately 60% of the genes whose expression was affected were the same whether infection was by MyRV1 or MyRV2, and all but one of those genes were altered in the same direction. Some of these groups of genes are in common with

those that are differentially regulated in cultures infected with the unrelated hypoviruses, but there are predictable differences. For example, hypovirus infection of *C. parasitica* results in female infertility, whereas mycoreovirus infection does not, and this is reflected in the expression of two genes predicted to be involved in the *C. parasitica* mating response. Both *mf2-1*, which encodes the fungal pheromone precursor, and *Csp12*, which encodes a homolog of the yeast *Ste12*-like transcription factor, were substantially downregulated in hypovirus-infected fungal isolates, which are female sterile, whereas there was much less effect on expression of these genes in either of the mycoreovirus-infected *C. parasitica* isolates. Virus is transmitted to ascospores at a rate of ~50% or less when the female parent is infected, but there is no virus transmission to ascospore progeny if the male parent in a mating is infected. Sequencing the complete genome of several strains of *C. parasitica* has been accomplished, and current investigations based on high-throughput RNAseq methodologies are underway.

Coinfections of Mycoreovirus and Other Viruses

Double infections of the well-characterized hypovirus CHV1/EP713 and MyRV1/Cp9B21 revealed that presence of the hypovirus caused an increase in both the concentration and the vertical transmission rate through conidia of the mycoreovirus, but that the mycoreovirus did not affect the concentration or transmission rate of the hypovirus. Furthermore, transgenic expression of only the hypovirus protein p29 also resulted in increased accumulation and transmission of MyRV1/Cp9B21. This is consistent with evidence that p29 serves as a suppressor of RNA silencing (= RNA interference) during hypovirus infection, and that this effect acts in trans to support enhanced mycoreovirus replication.

Coinfection of *C. parasitica* with CHV4 was recently shown to facilitate infection with MyRV2. Single infections of either the original host strain, C-18, or the commonly used virus-free strain EP155 with MyRV2 were less stable upon serial subculture than were the same strains when co-infected with CHV4, which itself is symptomless but stable in *C. parasitica*. Using *C. parasitica* mutants defective in the dicer-like gene *dcl2*, which is an integral component of the fungal RNA silencing-based defense response against virus infection, it was shown that the putative silencing suppressor of CHV4 was responsible for trans-stabilization of MyRV2.

SsReV1 was also first identified as a coinfection with another virus. In this case, a bipartite dsRNA virus was identified along with the 11-segment reovirus in *S. sclerotiorum* isolate SCH94. The doubly-infected isolates had a distinct colony morphology compared to virus-free isolates, but isolates infected with only SsReV1 were indistinguishable from uninfected isolates, indicating that SsReV1 alone did not have a discernable effect on the fungus. Unlike the above case with MyRV2, there was no evidence that SsReV1 was unstable without its original coinfecting virus.

Mycoreovirus Genome Rearrangements

Numerous alterations and rearrangements of mycoreovirus genome segments have been identified and characterized. The first of these, discussed above, involves complete loss of segment 8 of MyRV3 in some fungal isolates. As far as we are aware, this is the only example of contemporary observed loss of an entire reovirus segment. Whether this segment is dispensable because it is not required for virus infection of the fungus in culture or because it is required for infection of an as-yet unknown arthropod host is unknown.

Other segment alterations and rearrangements have been characterized during experimental infection of MyRV1. These include deletion of part or all of specific coding regions and duplication of all or part of coding regions of specific segments. Some of these segment alterations occurred in isolates singly-infected with MyRV1, some resulted in isolates coinfecting with MyRV1 and the hypovirus CHV1, and some from MyRV1 infection of transgenic fungal isolates expressing the p29 RNA silencing suppressor protein. Many of the MyRV1 segment mutants are associated with growth phenotypes and differences in viral RNA accumulation.

Coding region duplication among MyRV1 segments is an interesting phenomenon that has not been observed in other systems. When MyRV1 is influenced by the CHV1 silencing suppressor p29, in-frame extensions of the coding sequences of segments 1, 2, 3, and 6 have been observed, resulting in predicted larger protein products from those segments. Each of these products is predicted to be a structural protein, and while the predicted longer than wildtype proteins have been observed, in infected cells, it is not yet known whether and how these might be incorporated into particles. This type of segment coding region extension is unusual: in observed coding region duplications within rotaviruses, the most thoroughly studied example of such rearrangements, the size of the expressed coding region is not extended in-frame, but rather a second coding region is inserted head-to-tail downstream of the segment's unaltered cognate coding sequence. Such rearrangements would not be predicted to alter the natural coding sequence of the rearranged segment.

Deletions in MyRV1 segments 4 and 10, which are non-structural proteins, are tolerated. These deletions may be in-frame, resulting in a predicted fusion gene product, or out-of-frame, resulting in predicted truncated gene products. Surprisingly, virus that contains complete replacements of both segments 4 and 10 with their deletion mutant counterparts is viable, probably representing the only known example of a reovirus mutant that can tolerate loss of coding capacity of two segments. Also interesting is that this double deletion mutant replicates to similar levels as wildtype MyRV1.

The next step in mycoreovirus research is to develop a robust reverse genetics system to complement studies such as those above. Furthermore, discovery and characterization of new members of the genus *Mycoreovirus* – and similar fungal reoviruses – will continue as high throughput sequence-based methods dominate the realm of virus discovery.

Glossary

Biological control A method to prevent pests and parasites using beneficial organisms, here specifically means using mycovirus to control fungal diseases.

Hypovirulence Reduced virulence of a fungal pathogen caused by the infection of mycovirus; Hypovirulence and hypovirus of chestnut blight/*Cryphonectria parasitica* system

is a classic example for studying mycovirus and biological control of plant fungal diseases.

Mymonaviruses A group of mononegaviruses that was originally identified from a fungus.

Sclerotinia sclerotiorum An ascomycetous pathogen that can attack more than 400 species and subspecies of plants.

Introduction

The mycovirus was first discovered by Hollings in 1962 from a diseased mushroom, *Agaricus bisporus*. In the same year, an active substance capable of stimulating the production of interferon in mammals was found in *Penicillium* spp., and this substance was identified as double-stranded (ds)RNA which was extracted from mycovirus particles. The dsRNA elements also were found in a hypovirulent strain of chestnut blight pathogen (*Cryphonectria parasitica*) at 1970s. The dsRNA elements represented the first identified virus (hypovirus) which are devoid of coat protein. These studies led to a notion that the genome of the fungal virus is dsRNA. Since then, dsRNA became a marker for mycoviruses and was used to judge whether a fungal strain was infected by mycoviruses or not still today. DsRNA extraction screening with cellulose has detected a group of mycoviruses from various fungi, which produce dsRNA, as their genomes or replicative forms, in infected cells. Some of these viruses are phylogenetically related to plant single-stranded, positive-sense RNA (+ ssRNA) and are capsidless. Such fungal RNA viruses exemplified by hypoviruses and endornaviruses are now classified as + ssRNA viruses, rather than as dsRNA viruses, by the International Committee on Taxonomy of Viruses (ICTV). By recent high-throughput RNA sequencing or RNA Seq of hypovirulent strain AH98 of *Sclerotinia sclerotiorum*, an important necrotrophic ascomycetous pathogen that attacks numerous dicotyledonous plants, we found that strain AH98 was infected by a negative-stranded (–) RNA virus, designated as *Sclerotinia sclerotiorum* negative-stranded RNA virus 1 (SsNSRV-1). This is the first discovery of a -ssRNA virus as an infectious entity. Meanwhile, Dr. H. Kondo's research group in Japan discovered the incomplete sequence of L-protein-like gene in the genome of the powdery mildew fungus by performing an exhaustive search using sequences of known negative-strand RNA viruses. They also found two entire L-protein genes and one partial gene of unknown mononegaviruses present in two independent transcriptomic data of *Clariireedia* (*Sclerotinia*) *homoeocarp*. In 2016, these findings led ICTV to create the new family *Mymonaviridae* within the order *Monogavirales* containing one genus *Sclerotimonavirus* with *Sclerotinia sclerotimonavirus* as the type species, the exemplar virus of which is SsNSRV-1. The name *Mymonaviridae* is originated from *Myco* and *Mononegavirales*.

Phylogenetic Status of *Mymonaviridae* and its Related Families

The family *Mymonaviridae* belongs to the order *Monogavirales* (class *Monjiviricetes*, subphylum *Haploviricoyina*, phylum *Negarnaviricota*, realm *Riboviria*). Based on the phylogenetic analysis using the full-length L protein (RNA replicase), the members of *Mymonaviridae* are closely related to those of *Lispiviridae*, *Paramyxoviridae*, *Filoviridae*, *Pneumoviridae* and *Rhabdoviridae*, and are also phylogenetically related to members of *Nayamiviridae*, *Bornaviridae*, *Xinmoviridae*, *Artoviridae* and *Chuviridae*. Currently, there is only one genus (*Scleromonavirus*) in this family, however, the members in *Mymonaviridae* can be grouped into three clusters, and more genera should be established possibly to adopt viruses which are significantly different from those in *Scleromonavirus* (Fig. 1).

Species and Tentative Species in the Family *Mymonaviridae*

At present, the genus *Scleromonavirus* has seven species, namely *Sclerotinia sclerotimonavirus*, *Hubei sclerotimonavirus*, *Drop sclerotimonavirus*, *Dadou sclerotimonavirus*, *Illinois sclerotimonavirus*, *Glycine sclerotimonavirus* and *Phyllosphere sclerotimonavirus*. However, it is clear that there are additional eight viruses at least; *Penicillium cairnsense* negative-stranded RNA virus 1, *Narnavirus* sp.-QDH90729.1 (tentative name), *Lentinula edodes* negative-strand RNA virus 1, *Penicillium adametzoides* negative-stranded RNA virus 1 or *Alternaria tenuissima* negative-stranded RNA virus 1 represents novel species; *Botrytis cinerea* mymonavirus 1 and *Sclerotinia sclerotiorum* negative-stranded RNA virus 7 together represent a novel species, and TSA1, -2, -3 from *Clariireedia homoeocarpaa* may also represent a novel species (Table 1).

Fig. 1 Phylogenetic analysis of members and tentative members in the family *Mymonaviridae* and other related families by Maximum Likelihood method. The viruses whose complete sequence of RNA replicase is known were selected to construct this phylogenetic tree. In total 83 RNA replicase sequences from viruses in the order *Mononegavirales* were analyzed. The phylogenetic analyses were conducted in MEGA7 (Kumar, S., Stecher, G., Tamura, K., 2016. Molecular Biology and Evolution 33,1870–18742). Bootstrap numbers out of 1000 replicates are indicated at the nodes. Virus name and accession number were on the right at the correspondence position.

Table 1 List of members and tentative members in the family *Mymonaviridae*

^aThis virus is most likely to incorrectly be named, narnaviruses that belong to the family *Narnaviridae*, with + ssRNA genomes of <3.0 kb.

^bShTAS1, -2, -3 are not really virus names, but are names for transcriptome shotgun assemblies from *Sclerotinia homoeocarpa* (renamed as *Clariireedia homoeocarpa*).

Virion

So far, virion morphology of SsNSRV1 virus and *Fusarium graminearum* negative-stranded RNA virus 1 (FgNSRV-1) has been defined, whereas the virions of other viruses are still unknown. The morphology of virions of SsNSRV1 and FgNSRV-1 is similar. SsNSRV-1 virions are filamentous, 25–50 nm in diameter and about 1000 nm in length, while FgNSRV-1 particles are 35–50 nm in diameter and about 1200 nm in length. The virions have enveloped-like structures (EVLS), which are similar to the virion of viruses in the family *Filoviridae*, but lacking spikes on the surface. When the virion is broken, Nucleocapsid complexes (RNPs) are released. RNPs are filamentous, branched, left-handed, and helical structures with tight or loose coils. RNPs of SsNSRV-1 have a diameter of 20–22 nm and a length of 400–2000 nm, while the size of RNPs is unknown for FgNSRV-1. Nucleocapsid consists of polymerized Nucleoprotein (N) monomers (Fig. 2).

The Genomic Structure

Since the full-length genome sequences of some viruses are not available and novel viruses with larger or smaller genomes than the fully-sequenced mymonaviruses are frequently discovered, the size range of viral genome cannot be accurately determined.

Fig. 2 Morphology and structure of virions of *Sclerotinia sclerotiorum* negative-stranded RNA virus 1 (SsNSRV-1). (A) Filamentous, possibly enveloped virions (marked by arrowheads), and nucleoprotein-RNA complexes (RNPs). (B) Purified tight (left) or loose (right) coils of RNPs. (C) Rings that make up the coils and nucleoprotein (NP) monomers (marked by arrowhead). Virions and RNPs were purified from mycelia of strain AH98 and virus-transfected strain Ep-1PNA367-PT2 of *Sclerotinia sclerotiorum* and negatively stained with 2% PTA [(wt/vol), pH 7.4]. Reproduced from Liu, L, Xie, J, Cheng, J, *et al.*, 2014. Fungal negative-stranded RNA virus that is related to bornaviruses and nyaviruses. *Proceedings of the National Academy of Sciences of the United States of America* 111, 12205–12210.

From the current known viruses in the family *Mymonaviridae*, the genome size may be between 9000 and 11600 nt, and the largest virus in the genome is *Lentinula edodes* negative-strand RNA virus 1. There are 5–7 open reading frames (ORFs) on the genome; SsNSRV-1 has six ORFs on its genome (Fig. 3(A)). There are conserved non-coding regions between genes. For example, in the SsNSRV-1 genome, the sequences of non-coding regions are (3′ – (A/U) (U/A/C) UAUU (U/A) AA (U/G) AAAACUUAGG (A/U) (G/U) – 5′) (Fig. 3(B)). The N protein is encoded by ORF II, and the L protein (RNA replicase) is encoded by ORF V. There is usually an ORF (ORF VI) following ORF V. The small ORF IV and ORF VI are undetectable in some mymonaviruses. The gene arrangement of mymonaviruses is different from that of other mononegaviruses. The most conserved L protein shares sequence similarity among those of different members of the same genus, whereas other proteins have no significant similarity among them. The functions of the N and L protein are determined, while the functions of other proteins are unknown. In fact, only the transcriptional pattern of the SsNSRV-1 genome is known: six ORFs can be transcribed independently, while ORF V and ORF VI are transcribed together (Fig. 3(C)). The genome of this family of viruses has occasionally defective RNA molecules. For example, in *S. sclerotiorum*, there are defective RNAs in which both 3′-terminus (including ORF I and ORF II, even ORF III) and 5′-terminus are deleted (Fig. 3(D)). It is likely that similar phenomenon occurs in other mymonaviruses and the "defective" RNAs replicate in fungi. *Botrytis cinerea* mymonavirus 1 has only three ORFs supports this notion. This observation may suggest that certain shorter version of the mymonavirus genomes, resulting from deletions of dispensable genes, are replication competent.

The Impact on the Host

The impact of mymonaviruses on their host is very difficult to determine. SsNSRV-1 was successfully transfected into a virus-free *S. sclerotiorum* strain by protoplast transfection. The pathogenicity of the strain infected with the virus showed a significant decline compared with the strain without the virus. *Botrytis cinerea* mymonavirus 1 was also found to have a significant inhibitory effect on the pathogenicity of its host *B. cinerea*; in addition, *Lentinula edodes* negative-strand RNA virus 1 may have an effect on the formation and development of fruitbody of the host shiitake mushroom (*Lentinula edodes*). FgNSRV-1 had no significant effects on the growth, pathogenicity, sporulation and toxin synthesis of the host *F. graminearum*. The impact of other members in the family *Mymonaviridae* has not been reported.

Fig. 3 Genome organization and characteristics of *Sclerotinia sclerotiorum* negative-stranded RNA virus 1 (SsNSRV-1). (A) Genome length and organization. Boxes indicate position and length of each ORF, which are labeled with Roman numerals, except for two ORFs, N (II) and L (V), which encode the nucleoprotein (N) and RNA-dependent RNA polymerase (L). A conserved domain in L is shown. (B) Alignment of the putative gene-junction sequences between ORFs in a 3'-to-5' orientation. Conserved sequences [3' - (A/U)(U/A/C)UAAU(U/A)AA(U/G) AAAACUUAGG(A/U) (G/U) - 5'] are highlighted in blue. Different shades indicate levels of conservations with the darkest color indicating the highest conservation. (C) Deduced transcription map based on 5'- and 3'-RACE. (D) Schematic diagrams for four defective genome RNA of SsNSRV-1, dotted lines represents deleted regions on the genome. Reproduced from Liu, L, Xie, J, Cheng, J, *et al.*, 2014. Fungal negative-stranded RNA virus that is related to bornaviruses and nyaviruses. *Proceedings of the National Academy of Sciences of the United States of America* 111, 12205–12210.

Host and Distribution

The hosts of viruses in family *Mymonaviridae* are mostly fungi, but two of them (tentatively called *Narnavirus* sp.-QDH90729.1 and -*Narnavirus* sp.-QDH88671.1) were identified from grassland soil, and Hubei rhabdo-like virus 4 was discovered from an arthropods or arthropods-associated organisms. It is interesting that *Narnavirus* sp.-QDH88671.1 belongs to the same species as Hubei rhabdo-like virus 4, suggesting that they may share the same hosts. Three viruses were identified from phyllosphere. It is considered that some viruses from phyllosphere are closely related to viruses from pathogenic fungi that grow on the same plants; hence, those viruses likely have fungal hosts.

Currently, it is known that viral strains of the species *Sclerotinia sclerotimonavirus* such as SsNSRV-1 are distributed widely in China; it is also detected in both the United States and Australia. SsNSRV-4 (species *Drop sclerotimonavirus*) is detected in

S. sclerotiorum in the United States and Australia. *Botrytis cinerea* mymonavirus 1 is distributed in 11 provinces of China and is also found in *S. sclerotiorum*. Hence, viruses in the family *Mymonaviridae* are widely spread around the world.

Glossary

Ribozyme RNA with a catalytic activity.

Introduction

The narnaviruses 20S RNA and 23S RNA (ScV20S and ScV23S, respectively) are positive strand RNA viruses found in the yeast *Saccharomyces cerevisiae*. These two viruses are ascribed to the genus *Narnavirus* of the family *Narnaviridae*. Massive RNA sequencing has started detecting many narnavirus-like sequences in plant and insect sources. Like other fungal viruses, 20S and 23S RNAs have no extracellular transmission pathway. They are transmitted horizontally by mating, or vertically from mother to daughter cells. It is believed that the high frequency of mating or hyphal fusion that occurs in the host life cycle makes an extracellular route of transmission dispensable for the viruses. The thick cell wall of fungi may also form a formidable barrier. The lack of extracellular transmission may, in turn, explain two prominent features found in narnaviruses. First, they are persistent viruses and do not kill the host cells. If their infection caused damages or disadvantages to the host, then the viruses might have perished during the course of evolution because of the lack of an escape route. Secondly, because there is no extracellular phase, the viruses do not need to form virions to protect their RNA genomes in the extracellular environment. In addition, they do not need machinery to ensure exit or reentry to a new host. The lack of a virion structure may sound peculiar to those who are familiar with infectious viruses. Considering that viruses are selfish parasites, however, it will be natural for them to shed genes or functions unnecessary for their existence. Consequently, the genomes of narnaviruses are simple and small: they only encode a single protein, the RNA-dependent RNA polymerase (RdRp). This may contribute to their persistence by reducing a number of viral proteins that might interfere with metabolism vital for the host. The simplicity of their RNA genomes encoding a single protein, together with the development of 20S and 23S RNA virus launching systems from yeast expression vectors, makes narnaviruses a good model system to investigate replication and the molecular basis for intracellular persistence of RNA viruses.

Historical Background

20S RNA was first described in 1971 as a single-stranded RNA (ssRNA) species that accumulated in yeast cells transferred to 1% potassium acetate, a standard procedure to induce sporulation in yeast under nitrogen starvation conditions. Because of its mobility relative to 25S and 18S rRNAs, the species was named 20S RNA. Later it was found, however, that the accumulation of 20S RNA was not related to the sporulation process because haploid cells that do not sporulate also accumulate 20S RNA under nitrogen starvation conditions. It was also found that 20S RNA is a cytoplasmic genetic element. The realization of 20S RNA as a viral entity, however, had to wait several years, until the characterization of 20S RNA by cloning and sequencing in 1991. 23S RNA was reported first time in 1992. Both viruses were recognized as members of a new family, *Narnaviridae* (naked RNA virus), a taxonomic group that appeared first time in the 2000 edition of the ICTV report. The other genus in the family is *Mitovirus*, whose members are found in mitochondria of fungi, many of them are pathogenic to plants. All members of the family have small RNA genomes (2–3 kilobases) that encode single proteins, their RNA-dependent RNA polymerases, and reside either in the cytoplasm (narnaviruses) or in the mitochondria (mitoviruses) of the host.

Viral Genomes

Many laboratory strains of *S. cerevisiae* harbor 20S RNA virus and fewer strains contain 23S RNA virus. Both viruses are compatible in the same host. The presence of 20S and 23S RNA viruses does not confer phenotypic changes to the host. Under nitrogen starvation conditions, the amounts of the viral genomes become almost equivalent to those of rRNAs (>100,000 copies/cell; Fig. 1).

In contrast, vegetative growing cells contain much lower amounts of the viral RNAs (5–20 copies/cell). Fig. 2(A) shows the genome organization of narnaviruses. Both 20S and 23S RNAs are small (2514 and 2891 nt, respectively) and each genome encodes a single protein; a 91 kDa protein (p91) by 20S RNA and a 104 kDa protein (p104) by 23S RNA.

The 5' untranslated regions in both RNAs are extremely short: 12 nt in the case of 20S RNA and only 6 nt in 23S RNA. These RNAs lack poly(A) tails at the 3' ends. The same RNA can serve as template for translation and also for negative strands

Fig. 1 RNA extracted from nitrogen-starved yeast cells carrying none (1), 20S RNA virus alone (2), 23S RNA virus alone (4) or both viruses together (3), was separated in an agarose gel and visualized by Ethidium bromide-staining. 20S and 23S RNAs, together with the rRNAs are indicated.

Fig. 2 Genomic organization of 20S and 23S RNA viruses (A) and their launching plasmids (B). (A). Diagrams of 20S and 23S RNAs and the proteins encoded by them, p91 and p104, respectively. (A–D) represents motifs conserved among RdRps from positive strand and dsRNA viruses and 1–3 indicates amino acid stretches conserved between p91 and p104. (B). The complete cDNA of 20S and 23S RNA genome is inserted downstream of the constitutive *PGKI* promoter in a yeast expression vector in such a way that positive strands are transcribed from the promoter. The HDV ribozyme is adjoined directly to the 3' end of the viral genome.

synthesis. The antigenomic (or negative strand) RNAs have no coding capacity for protein and are present at much lower copy numbers (a few per cent) compared to the genomic (or positive strand) RNAs under the induction conditions. The double stranded forms of 20S and 23S RNAs are known and called W and T, respectively. These double-stranded RNAs (dsRNAs) accumulate when the cells are grown at 37°C, a rather high temperature for yeast (the optimal temperature for growth is about 28°C). These dsRNAs are not intermediates of replication but byproducts. Replication proceeds from a positive strand to a negative strand and then to a positive strand.

The proteins encoded in the viral genomes are not processed to produce smaller fragments with distinct functions. Both proteins contain amino acid motifs well conserved among RdRp from positive strand and double-stranded RNA viruses (**Fig. 2(A)**). Their RdRp consensus motifs are most closely related to those of RNA bacteriophages such as *Qβ*. In addition, p91 and p104 share stretches of amino acid sequences (denoted by 1–3 in **Fig. 2(A)**) in the same order throughout the molecules, indicating a close evolutionary relationship between these two viruses.

Ribonucleoprotein Complexes as a Viral Entity

Yeast is also a natural host for dsRNA totiviruses, called ScV-L-A and ScV-L-BC. Like narnaviruses, totiviruses have no extracellular transmission pathway. However, these viruses have *gag* and *pol* genes, and their dsRNA genomes are encapsidated into intracellular

viral particles. In contrast, 20S and 23S RNA viruses have no capsid genes to form virion structures. Then, how do these viruses exist inside the cell and establish a persistent infection without a protective coat? Earlier studies demonstrated that 20S RNA migrated as “naked RNA” in sucrose gradients. Furthermore, deproteination with phenol had no apparent effect on its mobility. Because protein provides a large part of the molecular mass in virions, these data clearly indicate that narnaviruses are capsidless. When specific antibodies against their RdRps became available, however, it was realized that each RNA genome is associated with its RdRp and this interaction is specific; that is, p91 is associated only with 20S RNA and p104 only with 23S RNA. These ribonucleoprotein complexes reside in the cytoplasm and are not associated with the nucleus, mitochondria, or intracellular membranous structures. Further studies indicated that most of the positive strands of 20S and 23S RNA viruses under induction conditions are associated with their own RdRps in a 1:1 stoichiometry. The complexes lack host proteins and can be formed even in *E. coli* if the RNAs and their RdRps are expressed from vectors. These complexes are called “resting complexes” to distinguish them from the “replication complexes” described in the following section. Negative strands are present at much lower amounts compared to positive strands. Available data indicate that they also form complexes with their own RdRps. These findings suggest that the formation of ribonucleoprotein complexes between the viral RNA and its RdRp is important for the life of 20S and 23S RNA viruses.

Replication Intermediates

Lysates prepared from virus-induced cells have an RNA-dependent RNA polymerase activity. The activity is insensitive to actinomycin D or α -amanitin, thus independent of a DNA template. The majority of *in vitro* products are positive strands of 20S RNA. Synthesis of negative strands accounts for a few percent compared to that of positive strands, thus reflecting the positive/negative strand ratio in the lysates. There is no, or very little, *de novo* synthesis *in vitro*. Therefore, radioactive nucleotides are unevenly distributed into 20S RNA positive strand products with more incorporation into the 3′ end region. Replication complexes that synthesize 20S RNA positive strands have a single-stranded RNA backbone and migrate in native agarose gels as a broad band corresponding to ssRNA in the size ranging from 2.5 to 5 kb long. These complexes consist of a full-length negative strand template (2.5 kb) and a nascent positive strand of less than unit-length, probably held together by the polymerase machinery. Deproteination with phenol converts them to double-stranded RNA. Therefore, W dsRNA is not a replication intermediate but a byproduct. It is likely that the high temperature (37°C) for growth may destabilize replication complexes, thus resulting in the accumulation of double-stranded RNA. Upon completion of RNA synthesis *in vitro*, the positive strand products as well as the negative strand templates are released from replication complexes. It is likely that, in the cell, the released negative strands are immediately recruited to another round of positive strand synthesis, because the majority of negative strands in lysates are present in replication complexes engaging in the synthesis of positive strands. Interestingly, both positive and negative strands released from replication complexes are associated with protein. Because replication complexes contain at least one p91 molecule per complex, p91 is a good candidate for the protein. Although resting complexes can be formed in *E. coli*, lysates prepared from these cells showed no viral RNA polymerase activity. It is likely that formation of replication intermediates requires a host factor(s).

Generation of Narnaviruses *in Vivo*

As mentioned earlier, the presence of narnaviruses does not render phenotypic changes to the host. This has hindered studies on replication or virus/host interactions using yeast genetics. This obstacle has been overcome by developments in generating 20S and 23S RNA viruses *in vivo* from a yeast expression vector (Fig. 2(B)). In either case, the complete viral cDNA was inserted in the vector downstream of a constitutive promoter in such a way that positive strands can be transcribed from the promoter. The 3′ end of the viral sequence was directly fused to the hepatitis delta virus (HDV) antigenomic ribozyme. Therefore, intramolecular cleavage by the ribozyme will create transcripts *in vivo* having the 3′ termini identical to the viral 3′ end. The efficiency of virus launching is high. Twenty to 70% of the cells transformed with the vector generated the virus. The primary transcripts expressed from the vectors have non-viral sequences (about 40 nt) at the 5′ ends. The generated viruses, however, possessed the authentic viral 5′ ends without the extra sequences. It is likely that the 5′ non-viral extension was eliminated by a 5′ exonuclease. Using these launching systems, it has been demonstrated that each RdRp is essential and specific for replication of its own viral RNA. Because negative strands cannot be decoded to the RdRps, vectors in which the viral cDNAs were reversed failed to generate the virus. These negative strand-expressing vectors, however, successfully generated narnaviruses, if active polymerases were provided *in trans* from a second vector. Therefore, both 20S and 23S RNA viruses can be generated from either positive or negative strands expressed from a vector.

Cis-Acting Signals for Replication

20S and 23S RNA genomes share the same 5 nt inverted repeats at the 5′ and 3′ termini (5′-GGGGC...GCCCC-OH). Extensive analysis was done modifying each nucleotide at the 3′ ends. It was found that the 3rd and 4th Cs from the 3′ termini are essential for replication in both viruses. While the 3′ terminal and penultimate Cs can be eliminated or changed to other nucleotides

Fig. 3 Comparison of the 3' terminal secondary structures in the positive (+) and negative (–) strands of 20S and 23S RNA viruses, with the top half domain of tRNA^{Tyr}. The non-templated A residues at the viral 3' termini are placed in parenthesis. The consecutive four Cs essential for replication are boxed (green). A second *cis*-signal (the mismatched pair of purines) present in the positive strand of 23S RNA virus is circled (green). Y, R, and N stand for pyrimidine, purine, and any base, respectively.

without affecting virus generation, the generated viruses recovered the wild type Cs at the termini. Therefore, the consecutive four Cs at the 3' terminus are essential for these viruses (Fig. 3).

In contrast, the G immediately upstream the 4 Cs from the 3' end is dispensable for replication in both viruses. 23S RNA virus requires an additional 3' *cis* signal for replication. The stem-loop structure proximal to the 3' end contains a mismatched pair of purines in the stem (Fig. 3). This mismatched pair is essential for replication but the virus tolerates any combination of purines at the pair. On the other hand, changing the purines to pyrimidines or eliminating one of the purines at the mismatched pair blocked virus generation. The distance between the mismatched pair and the 3' terminal four Cs and/or their spatial configuration appears to be critical, because shortening or increasing the length of the stem between the two sites by more than one base pair abolished virus launching. It is not known whether 20S RNA virus has a similar *cis* signal in the stem-loop structure proximal to the 3' end. The first G upstream the 4 Cs from the 3' end is located at the bottom of the stem structure. This G, as mentioned earlier, can be changed to another nucleotide without impairing replication, as far as the modified nucleotide is hydrogen-bonded at the bottom of the stem.

The negative strands of 20S and 23S RNA viruses also possess four consecutive Cs at the 3' ends. Using the two-vector system mentioned above, it has been found that the 3rd and 4th Cs from the 3' end are essential for replication. Similar to the positive strands, the 3' terminal and penultimate Cs can be eliminated or changed to other nucleotides without affecting virus generation and the generated viruses recovered the wild type four Cs at the 3' ends. Therefore, the consecutive four Cs at the 3' end of the negative strand are again a *cis* signal for replication. The 5' ends of viral positive strands have not been analyzed extensively. Elimination of the 5' terminal G or changing it to other nucleotide had no effect on virus generation and the generated viruses recovered this G at the 5' ends.

Cis-Signals for Formation of Ribonucleoprotein Complexes

Narnaviruses, as mentioned earlier, exist as ribonucleoprotein complexes in the host cytoplasm. In the absence of the HDV ribozyme, RNA transcribed from the launching vectors failed to generate viruses because of the presence of non-viral extensions at the 3' end. The transcripts, however, can be decoded to viral polymerases and the polymerases can form complexes *in vivo* with the transcripts, thus providing an assay system to analyze *cis*-signals for formation of ribonucleoprotein complexes. By immunoprecipitation with antiserum specific to p104, it has been found that the bipartite 3' *cis*-signal for replication (more specifically, the mismatched pair of purines and the 3rd and 4th Cs from the 3' end) is essential for 23S RNA positive strand to form complexes with the polymerase. In the case of 20S RNA virus, a similar *in vivo* assay indicates that the 3' *cis* signal for replication (in particular the 3rd and 4th Cs from the 3' end) is also important for formation of ribonucleoprotein complexes with p91. When isolated resting complexes of 20S RNA virus were analyzed *in vitro*, however, it was found that p91 physically interacts with 20S RNA at three different sites, not only at the 3' end but also at the 5' terminal and central regions of the molecule. The 5' binding site is located at the second stem-loop structure from the 5' terminus and is essential for replication. The central site interacts less strongly to p91 than the other two sites, and remains to be defined further. Computer-predicted analysis indicates that the 5' and 3' termini of 20S RNA (and 23S and 23S RNA and 23S RNANA) are brought together into close proximity by a long distance RNA/RNA interaction (Fig. 4). This may allow a single molecule of p91 to interact simultaneously with both ends of 20S RNA genome in a resting complex.

Narnavirus Persistence in the Host

mRNA degradation in yeast, like in other eukaryotes, is initiated by shortening the 3' poly(A) tail followed by decapping at the 5' end. Then the decapped mRNA is degraded by the potent Xrn1p/Ski1p 5' exonuclease as well as by a 3' exonuclease complex called exosome. The RNA genomes of narnaviruses, as mentioned earlier, have no 3' poly(A) tails, thus resembling intermediates of mRNA degradation. This suggests that these RNA genomes are vulnerable to the exonucleases involved in mRNA degradation. In fact, the copy numbers of 20S and 23S RNAs increase several-fold in strains having mutations in *SKI* genes such as *SKI2*, *SKI6*, and *SKI8*. These mutations were originally identified by their failure in lowering the copy numbers of L-A dsRNA totivirus and its satellite RNA M. It is known that the *SKI2*, *SKI6*, and *SKI8* gene products are components or modulators of the exosome. These

Fig. 4 Secondary structures at the 5' and 3' end regions of 23S and 20S RNA positive strands, as predicted by the MFOLD program. The AUG initiation codons (green) and the stop codons (red) for p104 and p91 are boxed. Stem-loop-II where the 5' binding site for p91 is located is shown. Note that about 150 nt from the ends in each viral genome there are inverted repeats of 8–12 nt long that bring both 5' and 3' ends to a close proximity.

observations suggest that the 3' end of the viral genome is constantly nibbled by 3' exonucleases. Therefore, one of the reasons for narnaviruses to form ribonucleoprotein complexes may be to protect their 3' ends from exonuclease cleavage. The fact that the 3rd and 4th Cs from the 3' end are important to form complexes in both viruses fits this hypothesis because binding of the RdRp to these nucleotides would block progression of the exonuclease and protect the internal region. As described earlier, mutations introduced at the terminal and penultimate positions at the 3' end had no deleterious effects on virus launching and the generated viruses recovered the wild type sequences. This suggests that the terminal and penultimate positions at the 3' ends are not only vulnerable to cleavages but also accessible to the repair machinery. The 3' ends of these viruses may undergo constant turnover at these positions.

It is not known whether the 3' end repair is carried out by the replicase machinery during the replication process, or by host enzymes. The following evidence may favor the latter case. The 3' terminal structures of 20S and 23S RNAs resemble a half of tRNA, the so-called "top-half" domain, consisting of the acceptor stem and T stem (Fig. 3). The domain provides the determinants necessary for specific interactions with tRNA-related enzymes such as the tRNA nucleotidyltransferase (CCA-adding enzyme). This raises the possibility that 20S and 23S RNAs nibbled at the 3' ends by 3' exonucleases are repaired to the wild type sequences by the CCA-adding enzyme. The fact that 15%–30% of both positive and negative strands of 20S and 23S RNAs possess an unpaired A at the 3' ends supports this possibility. Furthermore, that the 3' repair is confined to the terminal and penultimate positions is consistent with the catalytic activity expected for the CCA-adding enzyme.

Concerning the 5' end, the first nucleotides in both 20S and 23S RNAs are four consecutive Gs (Fig. 4). It is known that oligo G tracts inhibit progression of the Xrn1/Ski1 5' exonuclease. Furthermore, these consecutive Gs are buried at the bottom of a long stem structure in both viruses. These features suggest that 20S and 23S RNAs by themselves are resistant to the 5' exonuclease. This was confirmed by modifying the 5' terminal stem structure of 20S RNA. Destabilizing the stem structure severely affected 20S RNA virus generation from a vector in wild type cells, but the same vector successfully generated the virus in *SKI1*-deleted cells. Therefore, the 5' terminal stem structure is critical for the virus to evade *SKI1* surveillance. The initiation codon of p91 is located in the middle of the 5' terminal stem structure. If p91 bound to this stem in the ribonucleoprotein complex, then such a stable binding would interfere with translation of new p91 molecules from the RNA. In this context, it may make sense that the 5' binding site of p91 in the complexes is located at the second stem-loop structure from the 5' end. By binding simultaneously to this site and also to 3' end of the same RNA molecule, p91 may stabilize the long distance RNA-RNA interactions that bring the 5' and 3' ends of the RNA into proximity, and help the RNA to form an organized structure by further interacting with the central binding site. Furthermore, because the host cytoplasm is filled with a great variety of RNA molecules, formation of complexes between the viral polymerase and its template RNA may also facilitate its replication by discriminating non-viral RNAs as templates.

Phlegiviruses (Unassigned)

Karel Petrzik, Biology Center CAS, Institute of Plant Molecular Biology, České Budějovice, Czech Republic

Introduction

Although the first reported virus-associated fungal disease (La France disease) was described in the basidiomycete of the cultivated button mushroom, *Agaricus bisporus*, the vast majority of currently known mycoviruses are derived from ascomycetous fungi. Despite their rarity, the basidiomycete-infecting viruses are classified as belonging to several virus families including *Endornaviridae*, *Narnaviridae*, *Partitiviridae* and *Megabirnaviridae*. The exception is phlegiviruses, wherein all currently known viruses infect basidiomycetous hosts. Like many other mycoviruses, phlegiviruses are not associated with any adverse impact on fruiting bodies or mycelia. *Lentinula edodes* virus (LeV) dsRNA has been found in malformed cultures of shiitake mushroom and also in healthy-looking fruiting bodies and actively growing mycelia.

Although phlegiviruses have yet to be officially classified by the International Committee on Taxonomy of Viruses (ICTV), the genus “Phlegivirus” was proposed to accommodate previously described “phlegiviruses” belonging to 5 species (Table 1). Justification for creating the genus “Phlegivirus” is based on biological properties, percent sequence identity and similarity in genome size and organization. Furthermore, members of the proposed genus are distinctly different from other ICTV-recognized virus genera.

Virion Properties

Although repeated attempts were made to isolate virus particles from purified preparations of LeV, PgLV1, and RfV1, no viral particles have been observed by electron microscopy. A purification protocol using polyethylene glycol precipitation, ultracentrifugation, and sucrose gradient centrifugation has been successful in purifying dsRNA but not in isolating virions. At about 3539 nm, the length of the observed linear dsRNA corresponds to the genome size of about 11.8 kb for this virus. Most probably,

phlegiviruses are present in hosts as naked dsRNA and are somehow stabilized, perhaps by host proteins. Furthermore, the phlegivirus genomes do not code for capsid protein (CP) (Figs. 1 and 2).

Genome Organization

The monopartite dsRNA genome of phlegiviruses is about 11 kbp long and contains two large ORFs in different frames on the genomic plus strand. ORF1 encodes a protein with calculated molecular mass of about 200 kDa, and ORF2 encodes a protein with molecular mass in the range of 140–170 kDa. There are no in-frame stop codons upstream from the ORF2 start codon, but there is a ribosomal -1 frameshift sequence (AAAAAAA in TtV1, GGGAAAC in LeV, GGGUUUU in PgLV1, and AAAUUUC in RfV1) with a pseudoknot structure. This raises the possibility that ORF2 could be translated as a fusion protein with ORF1. The ribosomal

RdRp below diagonal, ORF1 above diagonal.
See [Table 1](#) for full names of viruses.

frameshift sequence has not been detected in PsVA, but stable stem-loop structures that could assist in pausing translating ribosomes were predicted in this virus close to the slippery site.

Polyprotein processing is intrinsic for many viruses. In phlegiviruses PgLV1 and TtV1, the picornavirus proteinase 2A^{Pro}-like motif was found on the N-terminal part of ORF1. This supports a hypothesis that the protein could be further processed by cleavage. This motif comprises the seven aa residues G/DxExNPG and the N-terminal proline of 2B protein ([Fig. 3](#)). The motif has been found also in *Rosellinia necatrix* mycovirus 2-W and in *Fusarium graminearum* hypoviruses 1 and 2. Based on the expected activity of 2A^{Pro}, the N-terminal 301 and 90 aa fragments of PgLV1 and TtV1 polyprotein, respectively, could be released.

The ORF1-encoded protein is unrelated to any protein in GenBank. In all phlegiviruses, however, there is a region having similarity to the NUDIX hydrolase domain (pfam00293) that is close to the N-terminal part of ORF1. NUDIX hydrolases constitute a diverse superfamily of pyrophosphatases that are widespread among eukaryotes, bacteria, archaea, and some viruses. They catalyze hydrolysis of nucleoside diphosphates with various substrate specificities and function to clear the cell of potentially deleterious endogenous metabolites. Previously, NUDIX domain has been found only in dsDNA poxviruses, but the NUDIX domain in phlegiviruses differs from that of the dsDNA viruses and forms a distinct cluster in phylogenetic analysis. With the exception of RfV1, one or more transmembrane domains are predicted on the N-terminal part of the ORF1 protein upstream from the NUDIX domain in all phlegiviruses.

ORF2 encodes a protein with calculated molecular mass of 140–170 kDa and having the RNA-dependent RNA polymerase (RdRp) catalytic domain. An S7-phytoreovirus-like domain is located in PgLV1, PsVA, and TtV1 close to the N-terminus of the ORF2-encoded protein. The phytoreovirus S7 domain is widely distributed in diverse dsRNA viruses within proteins known to be viral core proteins having nucleic acid binding activities. One can speculate that ORF2 encodes a structural protein that binds and protects the genomic RNA.

The 5'UTR region is 25 to 1154 nt long and the 3'UTR is 29–113 nt long. Disparity in the UTR sequences could be caused by deletions in the 5'UTR sequences. There is no polyadenylation or secondary structure on the 3' ends ([Figs. 4](#) and [5](#), [Table 2](#)).

Biological Properties

All phlegiviruses are associated with infections of basidiomycetes. In the case of PsVA, the mycorrhizal fungi have not been identified to species level, but they do sequence closely to a *Ceratobasidium* sp. and a *Rhizoctonia* sp. Like many other mycoviruses, phlegiviruses are not associated with an adverse impact on fruiting bodies or mycelia. LeV dsRNA has been found in malformed cultures of *Lentinula edodes* and also in healthy-looking fruiting bodies and actively growing mycelia. No correlation has been determined between LeV incidence and growth rate of the mycelium. Furthermore, the fact that more than 40% of monokaryotic progeny originating from the basidiospore of the fruiting body have been shown to contain LeV dsRNA indicates the persistence of dsRNA during sexual reproduction. The absence of capsid protein in phlegiviruses is speculated to be related to the feeding habits of the bark- and fungus-feeding beetles and oribatid mites (Acari), which can efficiently transfer the virus-infected fungus to a new environment. Thereafter, the CP would no longer be necessary for the virus to exit from the host cell, for its protection from the environment, and for it to create a new infection.

Evolutionary Relationships among Phlegiviruses

All five phlegiviruses have almost identical genome arrangements and are monophyletic in a maximum-likelihood phylogenetic tree inferred from the RdRp region between motifs I and VII of the polymerase ([Fig. 6](#)). ClustalW comparison has shown 41%–54% nt identity across the genomes. Amino acid identity among the homologous proteins was 12%–44% for ORF1 proteins and 12%–55% for RdRps ([Table 3](#)).

Megabirnaviruses (family Megabirnaviridae) are closely related to phlegiviruses, while chrysoviruses (family *Chrysoviridae*) and totiviruses (family *Totiviridae*) represent more distant groups as revealed by phylogenetic analysis based on RdRp. Megabirnaviruses differ, however, in genome components and their arrangement. They have two genome segments separately encapsidated in

isometric particles. dsRNA1 encompasses two overlapping ORFs. ORF1 encodes the CP and ORF2 encodes the RdRp, which is expressed as a fusion product with CP, probably via ribosomal frameshifting.

Future Perspectives

It seems highly probable that phlegiviruses translate their genome as polyproteins having molecular mass exceeding 350 kDa. The genomes of potyviruses, which possess genomic nucleic acids of similar length (about 10 kb) but positive ssRNA, is translated as a polyprotein that is cleaved by virus-coded proteinases up to 10 mature proteins. Neither protease motif nor putative cleavage sites have been identified, however, on either ORF1 or ORF2 of phlegiviruses, and thus the presence of a presumed cleavage enzyme (if one exists) remains obscure. The 7aa long motif resembling that of picornavirus proteinase 2A^{Pro} cleavage site has been found in two out of six viruses only, which makes it improbable that cleavage via this motif is important and common for this group.

Other than the RdRp, the presence of the NUDIX domain across all members of the proposed genus is the only constant feature of phlegiviruses indicating their origin from a common ancestor and supporting the phylogenetic relationships as inferred from the RdRp sequence. The role of this domain in the life-cycle of the viruses still needs to be clarified.

Glossary

Buoyant densities in CsCL Density, equal to that of CsCL. Determined by density gradient centrifugation (also called isopycnic centrifugation), a method to separate molecules in CsCL according to their density.

Mono-, bi- and tripartite Class of genomes: One, two or three individually packaged genome segments of a virus.

Monocistronic (m)RNA that contains one open reading frame with one initiation and one stop codon translated into one protein.

Negative-contrast electron microscopy Method, in which the background is more electron dense as the one of the object of interest, which thus is stained lighter than the background.

Post-transcriptional gene silencing (PTGS) Defense mechanism of plants in which dsRNA, e.g., originated from a virus, is degraded into small-interfering RNA which targets homologous ssRNA.

Root-nodules Structures located at roots of plants forming a symbiotic relationship with nitrogen-fixing bacteria.

Silencing suppressor (VSR) Viral suppressors of gene silencing: Proteins, that are able to inhibit the plant defense mechanism “Post-transcriptional gene silencing” (PTGS) at different steps.

Type species A Type Species is a species whose name is linked to the use of a particular genus name. The genus so typified will always contain the Type Species (Mayo *et al.*, 2002: “The Type Species in virus taxonomy”).

Introduction

Members of the family *Partitiviridae* (partitivirids) appear as small isometric particles with a size of 25–43 nm owning a segmented double-stranded (ds) RNA genome. They cause no symptoms in their hosts, are not mechanically or vectorially transmissible and can infect plants, fungi or protozoa. Partitivirids firstly discovered in 1968/69 by Pullen, were described as spherical, virus-like-particles (VLPs) with a diameter of about 28 nm. These VLPs occurred in apparently healthy sugar beet varieties and beet seeds. It was neither possible to transmit them to several herbaceous test plants via aphids or mechanical methods nor to remove them with heat therapy. During this time, the term “cryptic” was established. Kassanis *et al.* confirmed the wide distribution of this virus in beet species in 1977 and named it beet cryptic virus 1 (BCV1). They also discovered a high seed transmission rate in commercial beet varieties (90%), identifying non-infected beet species and establishing a purification method for BCV1. In 1980 two further VLPs with similar properties were discovered, *Vicia* cryptic virus (VCV) and carnation cryptic virus 1 (CCV1), both showing similar characteristics like BCV1. In 1981, Lisa *et al.* showed that the genome of CCV1 consists of segmented dsRNA. A few years later (1988) it was shown that isolated CCV1 particles own RNA-dependent RNA polymerase

(RdRp) activity catalyzing the synthesis of dsRNA in vitro. During this time period, Natsuaki's research group in Japan also discovered VLPs in plants designated as "temperate viruses", such as spinach temperate virus and beet temperate virus. It turned out that cryptic and temperate viruses are synonymous. In 1984 Kassanis proposed to retain the name module "cryptic" in order to distinguish these viruses from latent viruses, which in contrast to cryptic viruses are usually mechanically or vectorially transmissible. With the isolation of white clover virus 1, 2, and 3 (WCCV1, 2, and 3), Boccardo and team members were able to show that VLPs are indeed cryptic viruses and originate from the plant in which they replicate. The genome of these three viruses consists for each one of two dsRNA segments and confirms previous assumptions of a segmented genome. In the fifth ICTV report in 1991, the family *Partitiviridae* with the genus *Partitivirus* was included for the first time, in which cryptic and temperate viruses were classified. The criteria for this genus were: isometric particles and a genome consisting of two dsRNA species. Two years later, Xie *et al.* found a third cryptic virus in beet and named it beet cryptic virus 3 (BCV3). It was also possible to determine the nucleotide and derived amino acid sequence of one dsRNA segment and to identify it as a putative RdRp with conserved motifs that are also present in RdRps of other viruses. The taxonomy of the *Partitiviridae* changed in 1995–2000 with the sixth and seventh ICTV reports, in that the genus *Chrysovirus*, which contained two fungal infecting viruses, was assigned to the family. With the eighth ICTV Report 2005, this genus formed its own family, the *Chrysoviridae*, since the respective species had clearly characteristics distinguishable from the partitivirids, such as a genome consisting of four dsRNA segments. In 1995–2000, the family *Cryptoviridae*, containing plant-infecting cryptoviruses was removed and its genera *Alphacryptovirus* and *Betacryptovirus* inserted to the *Partitiviridae*. Members of these two genera are serologically and morphologically distinguishable. From then on more and more partitivirids were discovered and sequenced, for example in 2005 WCCV1 by Boccardo *et al.* and in 2007 VCV by Blawid *et al.* A milestone in the decoding of the 3D capsid structure was achieved in 2008 by the research team surrounding Ochoa through transmission electron cryomicroscopy and subsequent 3D reconstruction of the particles of the fungus-infecting gammapartitiviruses *Penicillium stoloniferum* virus S and F (formerly genus *Partitivirus*). In the following two years further structures were analyzed and in general the capsid is composed of 120 subunits consisting of 60 coat protein (CP) dimers in a T1-icosahedral symmetry. In the ninth ICTV report 2012, the new genus *Cryspovirus* was created in the family *Partitiviridae* named after the only protozoan infecting virus *Cryptosporidium parvum* virus 1, which was discovered in 1997 by Khramtsov *et al.*. By the availability of more sequence data from potential members of this family, better phylogenetic comparisons could be made and taxonomic restructuring was needed. Nibert *et al.* explained in 2014 that species from the genus *Partiti-*, *Alpha-*, and *Betacryptovirus* separated into four distinct clades, with two clades (now *Alpha-* and *Betapartitivirus*) simultaneously containing plant and fungal infecting species. As a result, in 2017 the changes were approved by the tenth ICTV report, listing the *Partitiviridae* with the genera *Alpha-*, *Beta-*, *Gamma-*, and *Deltapartitivirus* as well as *Cryspovirus*. To date, partitivirids have been discovered worldwide in fungi and plants (as well as in one protozoan) and due to modern high-throughput sequencing techniques their number is continuously increasing.

Current Taxonomy of the *Partitiviridae*

The family *Partitiviridae* currently comprises the five genera *Alpha-*, *Beta-*, *Gamma-*, and *Deltapartitivirus*, as well as *Cryspovirus*. The alpha- and betapartitiviruses include fungal as well as plant infecting species, whereas deltapartitiviruses infect plants and gammapartitiviruses fungi. The only species in the genus *Cryspovirus* infects protozoa. The phylogenetic tree, based on the amino acid sequences of the partitviral RdRps gives an overview about the taxonomic organization in this encyclopedia.

Overall, the family comprises 45 assigned members whereof 16 belong to the plant infecting species, 15 unassigned members comprising twelve plant infecting partitivirids and two unclassified, related fungal viruses. The unclassified but related viruses within the individual genera are listed separately. [Table 1](#) gives an overview of the composition of the individual genera.

To assign a species into the *Partitiviridae*, genus and species demarcation criteria have been established by the ICTV and need to be fulfilled. One of the criteria is the host, since the members of different genera may have different hosts (plants and fungi) or only one host (plants or fungi or protozoans). With regard to the genome segments and the proteins expressed, each genus has characteristic lengths and sizes. Additionally, there are guidelines for the percentage identity values between RdRp and CP amino acid sequences: Viruses assigned to different genera have a maximum RdRp amino acid sequence identity of less than 24%, different species show a amino acid sequence identity of less than 90% for the RdRp and less than 80% for the CP, respectively.

Until February 2020 there are 28 completely sequenced genomes of plant infecting species available in the NCBI GenBank. [Table 2](#) lists all assigned and unclassified but related plant infecting species with the respective sizes of genome segments and proteins as well as accession numbers.

Species, being suggested a member of the *Partitiviridae* which are not yet listed by the ICTV are shown in [Table 3](#).

Virion Properties

Partitivirids appear as small isometric particles, 25–43 nm in diameter in this encyclopedia. The capsid is composed of 120 subunits consisting of 60 dimers in a T=1-icosahedral symmetry. The viruses have at least two separately encapsidated genome segments encoding a RdRp and a CP. Partitivirids could be detected in numerous plant organs, for example stems, roots, cotyledons and petals. The virions are mainly located in the cytoplasm and less in the nucleus or nucleoli of parenchyma cells. Replication takes place in a semi-conservative mode.

Alphapartitivirus

Alphapartitiviruses are between 25 nm and 40–50 nm in diameter, the type species WCCV1 has an average size of 34 nm. In negative-contrast electron micrographs, the particles appear rounded and ring-shaped because the coloration penetrates in the middle (**Fig. 1**). The buoyant densities in CsCl of WCCV1 virions are 1392 g cm⁻³ and of VCV virions 1.37 g cm⁻³. Encapsidation is performed by a single major CP with a molecular weight of 51–57 kDa. The RdRp has sizes between 68 and 73 kDa. In case of *Raphanus sativus* cryptic virus 1, a third genome segment was found with so far unknown function.

Betapartitivirus

Members of the genus *Betapartitivirus* are between 25 nm and 38 nm in diameter. By negative-contrast electron microscopy WCCV2 appears as rounded particles, which are not penetrated by stain (**Fig. 2**). The buoyant density in CsCl of WCCV2 virions is 1.375 g cm⁻³ and analogous to the alphapartitiviruses there is also a single-major CP with a molecular weight of 71–77 kDa and an RdRp of 77–87 kDa. Betapartitiviruses have the largest proteins among all genera in this family.

isl.: isolate; VP: viral protein.

Cryspovirus

Cryptosporidium parvum virus 1 appears as isometric and non-enveloped virions of about 31 nm in diameter. Negative-contrast electron microscopy revealed single-layered particles, which are not penetrated by stain showing short protrusions on their surfaces. The buoyant density in CsCl is 1.39–1.44 g cm⁻³ and there is a single-major CP with a molecular weight of 37 kDa and an RdRp of 62 kDa.

Fig. 1 *Alphapartitivirus*. Negative-contrast electron micrograph of particles of an isolate of *White clover cryptic virus 1*, the type species of the genus *Alphapartitivirus*. The bar represents 50 nm. Reproduced from Ghabrial, S.A., Bozarth, R.F., Buck, K.W., Martelli, G.P., Milne, R.G., 2000. *Partitiviridae*. Fig. 2 *Betapartitivirus*. Negative-contrast electron micrograph of particles of an isolate of *White clover cryptic virus 2*. The bar represents 50 nm. Reproduced from Ghabrial, S.A., Bozarth, R.F., Buck, K.W., Martelli, G.P., Milne, R.G., 2000. *Partitiviridae*. In *Virus Taxonomy: Seventh Report of the International Committee on Taxonomy of Viruses*, New York: Academic Press, pp. 503–513.

Deltapartitivirus

Deltapartitivirus particles of PCV1 and PCV2 are approximately 30 nm in diameter. Like the betapartitiviruses, these particles are not penetrated by stain in negative-contrast electron micrographs and the buoyant density in CsCl of BCV2 was defined as 1.36 g cm^{-3} . The single major CP ranges in molecular weight from 38 to 49 kDa and the RdRp is approximately 54 kDa. A putative member of this genus, *Cucumis melo cryptic virus*, which was recently described, shows a longer dsRNA2 encoding a CP of 55 kDa. Beet cryptic virus 2 and *Fragaria chiloensis cryptic virus* (isl. NCGR CFRA 9089), *Raphanus sativus cryptic virus 2* and rose cryptic virus 1 (isl. ShB-1) contain a third genome segment, the function of which has not yet been conclusively clarified.

Genome Organization and Replication Strategy

Genome Organization

Members of the family *Partitiviridae* have at least two monocistronic genome segments, in few cases a third segment could be detected (see above). There are several theories about the function of this additional genome segment. Tzanetakis et al suggested in 2008 that due to the similarities of segments 2 and 3 of *Fragaria chiloensis cryptic virus*, Rose cryptic virus 1 and *Raphanus sativus cryptic virus 2* to each other, it could possibly be another CP, which was created by a duplication event that took place before species segregation. Thus, the CPs might have retained their function. Another hypothesis of Chen in 2006 was that they could be satellite elements. For the viruses BCV2 and rose cryptic virus 2 it was possible to detect strains in plants which do not contain the third segment. In a review by Nibert et al in 2014 it was suspected that the strains with the additional CP-like segment were present in a mixed infection and the associated RdRp could not yet be detected or was lost. If the RdRp had been lost, the other RdRp would have to be able to replicate all dsRNA segments.

The sizes of the two main genome segments of partitivirids are different between the genera and specific for the respective one. Table 4 gives an overview of the ranges of genome and protein sizes, respectively, from segments 1 and 2 (taken from Table 2 in Section “Current Taxonomy of the *Partitiviridae*”).

A schematic representation of the alphapartitviral genome of *Vicia cryptic virus* is shown in Fig. 3.

5' and 3'UTRs

The 5'UTRs of partitivirids show some genus-specific conserved sites, which is shown exemplarily in Fig. 4 for the alphapartitiviruses. The 5'UTRs of both dsRNA segments of the assigned species BCV1, CCV, VCV, and WCCV1 were aligned and 100% conserved regions are shown black-shaded. Gray-shaded sequences are not conserved in all viruses. In the case of WCCV1 the

Table 4 Overview of the ranges of genome and protein sizes from segments 1 and 2. (taken from Table 2 in Section “Current Taxonomy of the Partitiviridae”)

Genus	dsRNA1 [bp]	dsRNA2 [bp]	RdRp [aa]	CP [aa]
<i>Alphapartitivirus</i>	1866–2013	1708–1837	573–621	487–505
<i>Betapartitivirus</i>	2390–2444	2266–2354	723–746	672–674

**Fig. 3** Schematic genome organization of the alphapartitivirus *Vicia cryptic virus* (NC_007241.1, NC_007242.1). The RNA is represented by a black bar on which the open reading frames are illustrated as green (RdRp) and blue (CP) boxes. The numbers outline the first nucleotide position of the respective feature.**Fig. 4** Alignment of alphapartitviral 5'UTRs of both dsRNA segments. Areas with 100% identity are black-shaded and gray-shaded sequences are not conserved in all viruses. *BCV1*: beet cryptic virus 1; *CCV*: carrot cryptic virus; *VCV*: *Vicia cryptic virus*.

5'ends differ from the two dsRNA segments, which could possibly be due to the fact that not all nucleotides could be determined correctly. It is noteworthy, that all 5'UTRs of the second genome segments are longer.

Similar findings were described in the 5'UTRs of betapartitiviruses, which almost all begin with the pentanucleotide AGAUIU and show a highly conserved region at positions 39–56 (Fig. 5).

Furthermore, two conserved stem-loop structures are present, potentially being involved in dsRNA replication and/or virion assembly (Fig. 6).

Deltapartitiviruses seem to have three different types of extreme 5'ends (assuming all ends have been correctly determined). For example, nearly all tripartite species despite of BCV2 (FCCV, RSCV2, and RCV-1) begin with the septanucleotide GAUAAUG (Fig. 7, type 1). There is another variation in which the genome segments of most bipartite species (PCV 1 & 2, BCV2, and RNA2 of PeCV) begin with AGAAUU (type 2). Only FCV and RNA1 of persimmon cryptic virus show the nucleotides GGA(A/U)U at the 5'end (type 3). The 5'UTR of *Cryptosporidium parvum* virus 1 does not fit to one of these types and both segments start with GGAAA(A/G).

Fig. 5 Alignment of betapartitviral 5'UTRs of both dsRNA segments. Areas with 100% identity are black-shaded and gray-shaded sequences are not conserved in all viruses. *CCCCV2*: crimson clover cryptic virus 2; *CCV*: Cannabis cryptic virus; *DCV2*: dill cryptic virus 2; *HTCV2*: hop trefoil cryptic virus 2; *PmV1*: Primula malacoides virus 1; *RCCV2*: red clover cryptic virus 2; *WCCV2*: White clover cryptic virus 2.

Fig. 6 RNA foldings of partial 5'UTRs (nucleotides 1–54) of RCCV2 dsRNA1 (A) and dsRNA2 (B).

Within the 3'UTRs, there are less conserved sequences than it was shown for the 5'UTRs before. The 3'UTRs of alpha- and betapartitiviruses show poly(A) stretches, which can be interrupted by other nucleotides, deltapartitiviruses and *Cryptosporidium parvum* virus 1 lack this feature (Fig. 8). In general, these A-rich areas seem to be longer in RNA2 than in RNA1. From these findings the question arises, if this could be an imitation of common poly(A) tails. Additionally, the adenosine content of the last 3' located 50 nucleotides is significantly higher in alpha- and betapartitivirids than in the other genera. Betapartitiviruses show another relatively conserved feature - they end with three to four Cs at the extreme 3' end (Fig. 8).

RNA1& 2

In general, RNA1 is larger than RNA2 and encodes an RdRp. The size differs between the genera, so the RdRps of alphapartitiviruses are about 72 kDa in size, of betapartitiviruses about 87 kDa, of CSpV1 62 kDa and of deltapartitiviruses about 54 kDa. There are several

Fig. 7 Comparison of three different types of 5' ends of deltapartitiviruses (not aligned). Areas with 100% identity are black-shaded. Gray-shaded sequences are not conserved among all viruses. *BCV2*: beet cryptic virus; *FCV*: fig cryptic virus; *FCCV*: *Fragaria chiloensis* cryptic virus; *PCV1/2*: pepper cryptic virus 1/2; *PeCV*: persimmon cryptic virus; *RCV1*: rose cryptic virus 1; *RscV2*: *Raphanus sativus* cryptic virus 2.

Fig. 8 3' poly(A) stretches (underlined) and terminal located Cs (edged) of both segments of one alpha- and betapartitivirus. *VCV*: *Vicia* cryptic virus, α ; *WCCV2*: *White clover* cryptic virus 2, β .

known motifs that occur in RdRps of partitivirids. Motifs I and II are not exactly localizable, but motifs III to VIII can be determined with slight variations and examples are given for WCCV1 (α), WCCV2 (β), CSpV1 (*Cryspovirus*) and PCV1 (δ). Motif III can be detected as K-X-R-3X-(A,G,P), motif IV as D-W-2X-(F, Y)-D, motif V as G-(I, V)-X-S-G, motif VI as G-D-D, motif VII as I-(G, S, V)-Y, and motif VIII as R.

The smaller RNA2 encodes a CP with sizes of about 54 kDa for alphapartitiviruses, 75 kDa for betapartitiviruses and 37 kDa for CSpV1. In case of the deltapartitiviruses there seem to be two types of CP which can be distinguishable by size, one is about 49 kDa and the second one about 38 kDa. Compared to the RdRps, there are not so many clearly conserved sequence stretches to be found in the CPs. Some motifs are described, the first of which is called "SQLY" and varies a lot between different species and genera. A second motif "PGPL3XF" can be found in alphapartitiviruses and in a deviant form in CSpV1.

Replication Strategy

In the plant cell, dsRNA usually triggers RNAi as plant defense mechanism leading to post-transcriptional gene silencing (PTGS), which is responsible for its degradation. To circumvent this defense strategy, viruses have evolved silencing suppressors (VSRs). No VSR could be detected for partitivirids yet, so they are believed to perform their transcription/replication within the particle. Every virus particle contains one or two RdRp molecules anchored to the CP as well as one or two dsRNA segments either coding for the CP or the RdRp. The RdRp acts in a semi-conservative manner, producing plus-strands from the minus-strand in this encyclopedia. In a 3D reconstruction of the capsid of the PsV-S, possible pores could be discovered that are probably associated with the transport of the plus-strand RNA from the particle into the cytoplasm during transcription. The newly synthesized plus-strands remains in the particle while the parental plus-strand is released into the cytoplasm. There, translation of RdRps and CPs by cellular ribosomes takes place and packaging of new virions is performed. Therefore, RdRps and RNAs associate and interact with the CPs whereupon the particle is fully assembled. Protein-protein interaction studies of alpha- and betapartitiviruses revealed varying results. For example, the expected interaction between RdRp and CP could only be demonstrated for alphapartitiviruses and not for betapartitiviruses. Furthermore, in the case of alphapartitiviruses, the CP dimers seem to be located in the nuclear membrane, those of betapartitiviruses in inclusions within the cytoplasm of epidermis cells. These findings indicate different replication strategies and still have to be elucidated.

Transmission

Partitivirids are not able to be transmitted mechanically, by grafting or natural vectors. Within the plant or protozoon, no cell-to-cell movement is observed except during cell division or gamete fusion in case of CSpV1. From one plant to another partitivirids can be transmitted by seeds, ovules and pollen in high rates. It was found in crosses of BCV infected and non-infected sugar beet plants

(either female or pollen) that a female non-infected plant crossed with pollen from an infected plant led to an infection rate in progeny plants of 43% and vice versa of 82%. When both plants were infected, the infection rate in progeny plants is 100%. Partitivirids can not be eliminated by meristem culture or thermotherapy and stay life-long in their hosts. In experiments on *Dianthus* Szego and colleagues showed that after 16 years of in vitro cultivation carnation cryptic virus 1 (CCV1) was still present in the plants.

Virus-Host-Interaction

An infection with partitiviruses is asymptomatic, which is also referred to as a latent infection. To date, there is hardly any evidence of the effects that partitiviruses have on their host. One study, however, showed that the expression of the gene TrEnodDR1 from *Trifolium repens* in *Lotus japonicus* resulted in reduced growth of the transformants and a smaller number of root nodules formed by infection with *Mesorhizobium loti* due to an increase of endogenous abscisic acid. Within this gene, sequences corresponding to the CP gene of WCCV1 were detected, leading to the conclusion that an infection of *T. repens* with WCCV1 could be mutualistic. Another study screened perennial ryegrass concerning salt toxicity and one result was a clone containing a partial sequence of a RdRp from the putative deltapartitivirus RsCV2. These findings may suggest evidence for mutualistic relationships between plants and partitivirids. This effect does not seem to be limited to plants only, because there are also studies in the case of CsPV1 whose results indicate that strain-dependent increased virus concentration in its protozoan host is associated with increased *C. parvum* replication in cell cultures and higher oocyte count in dairy calves.

Another impact on the host plant is the horizontal gene transfer. It has been shown that CP-like sequences are present in *Arabidopsis* and *Nicotiana* species. However, most inserts are pseudogenes with internal stop codons. It has also been reported that in infected plants no inserts could be detected in the genome.

Glossary

Quadrupartite virus Virus with the four genomic segments separately packaged into four different particles.

Quadrupartite genome The essential genome is separated into four genomic segments.

$T = 1$ icosahedral symmetry Symmetry of capsid composed of 60 subunits, which forms 12 pentameric capsomeres.

Introduction

Screens involving filamentous fungi, particularly phytopathogenic fungi, have detected an enormous number of novel mycoviruses (or fungal viruses) that have unique biological and molecular features, and that enhanced our knowledge of virus diversity and evolution. Many of them have double-stranded RNA (dsRNA) genomes and isometric particles. DsRNA mycoviruses are currently classified into six families, *Chrysoviridae* (includes both traditional chrysovirus with four segments as well as proposed others with three to seven segments), *Megabirnaviridae* (two segments), *Partitiviridae* (mostly two segments), *Quadriviridae* (four segments), *Reoviridae* (11 or 12 segments), and *Totiviridae* (nonsegmented), and one genus *Botybirnavirus* (two segments, family unassigned). Some dsRNA mycoviruses have also been proposed as the members of tentative families or genera, such as *Alternaviridae* (four segments), *Fusagraviridae* (nonsegmented), *Megatotiviridae* (nonsegmented) and *Phlegivirus* (nonsegmented), the virion morphology for which is largely unknown, except for alternaviruses. The *Quadriviridae* is a recently established virus family, and its members are non-enveloped spherical viruses with quadrupartite dsRNA genomes. The genus *Quadrivirus* within the family currently contains a single species *Rosellinia necatrix quadrivirus* 1. *Rosellinia necatrix quadrivirus* 1 (RnQV1) was discovered during a screen of over 1000 Japanese isolates of the white root rot fungus, *Rosellinia necatrix* (class Sordariomycetes), which is an ascomycete able to infect over 400 plants. The name quadrivirus originates from the 'quadrupartite' dsRNA genome. At present, no species demarcation criteria exist for the genus *Quadrivirus* since only one species has been assigned to this genus. The virion structure of quadriviruses has unique features as compared to those of other known dsRNA viruses. Quadriviruses appear to be phylogenetically closely related to totiviruses (members of the genus *Totivirus* with an unsegmented dsRNA genomes). The goals of this article are to give an overview of the features of the well-studied quadriviruses and compare them with those of tentative members of the family *Quadriviridae* and other related dsRNA viruses.

Virion Structure and Composition

The virion of RnQV1 is non-enveloped, isometric, about ~45 nm in diameter (Fig. 1) and likely separately packages each of the four dsRNA genome segments, which are 3.5–5.0 kbp in length. The buoyant densities of quadrivirus virion are not known. The size of quadriviruses are similar to that of chryso-, partiti-, totiviruses (25–43 nm) and megabirnaviruses (~52 nm), which also separately encapsidate their segments, but are much smaller than that of mycoreoviruses (~80 nm), which package all of their dsRNA segments into a single multi-layered virion. Most of spherical dsRNA mycoviruses have a single-shelled $T = 1$ capsid formed by 60 asymmetric homodimers of two capsid protein (a 120-subunit $T = 1$ capsid). An exception is the chrysovirus particle, which is composed of 60 copies of a single capsid protein with a duplicated helix-rich domain (a genuine $T = 1$ capsid). The RnQV1 capsids are comprised of 60 copies of heterodimers of two structural proteins, P2 (1356 or 1357 residues) and P4 (1061 or 1059 residues), which are encoded by dsRNA2 and dsRNA4, respectively, but P2 383-residue C-terminal region is absent in the mature viral particle (Fig. 2). The P2-P4 heterodimers are organized in a quaternary structure similar to that of reovirus, chrysovirus and totivirus. The two structural proteins of RnQV1 isolate W1075 are cleaved into several polypeptides without altering capsid structural integrity, likely during virion purification and/or in the infected fungal host, whereas in isolate W1118 P2 and P4 remain nearly intact (Fig. 3(a)). Similar capsid assembly involving two structural proteins may be suggested for botybirnaviruses, *Botrytis porri* RNA virus 1 and *Alternaria alternata* botybirnavirus 1 and for a betachrysovirus, *Magnaporthe oryzae* chrysovirus, which possibly belongs to the newly proposed genus *Betachrysovirus* (currently designated Cluster II) of the family *Chrysoviridae* (see Fig. 5 for their phylogenetic relationships). Posttranslational cleavage/degradation similar to RnQV1-W1075 virions was also observed for the two putative structural proteins of these dsRNA mycoviruses, even though their structural characteristics are still unclear.

RnQV1 P2 and P4 lack sequence similarity, but they have a similar α -helical domain that is the structural signature shared with most dsRNA viruses. In addition to organizing the viral genome and RNA-dependent RNA-polymerase (RdRp) molecules, P2 and

Fig. 1 Quadrivirus particle structure. Electron micrograph of negatively stained particles of RnQV1-W1118 (scale bar, 100 nm).

Fig. 2 Three-dimensional cryo-EM reconstruction of RnQV1 virions at 3.7 Å resolution. (a) Radially color-coded surface-shaded virion $T = 1$ capsid viewed along an icosahedral two-fold axis showing 12 outwardly protruding decamers (orange). Bar = 100 Å. (b) Ribbon diagrams of P2 (blue) and P4 (yellow) proteins (top view). N and C termini are indicated. Symbols indicate icosahedral symmetry axes. (c) Surface-shaded virion $T = 1$ capsid viewed along an icosahedral two-fold axis highlighting the A (blue) and B (yellow) structural subunits. P2 C-terminal regions are clearly seen as hooks embracing P4 outer surface. Reproduced from Fig. 1(f) of Mata, C.P., Luque, D., Gómez-Blanco, J., *et al.*, 2017. Acquisition of functions on the outer capsid surface during evolution of double-stranded RNA fungal viruses. *PLoS Pathogens* 13, e1006755.

P4 may have acquired new functions by inserting complex domains in preferential insertion sites at the capsid outer surface, likely related to enzyme activity. The P2 insertion has a fold similar to that of gelsolin and profilin, two actin-binding proteins with a function in cytoskeleton metabolism, whereas the P4 insertion suggests protease activity involved in cleavage of the P2 C-terminal region.

Except for reoviruses, whose 10–12 dsRNA genome segments densely packaged within a single particle (~ 40 bp/100 nm³ that corresponds to a spacing between dsRNA strands of 25–30 Å), most of the known multi-segmented dsRNA mycoviruses have a multi-particulate nature, in which dsRNA segments are encapsidated separately and they might have a lower density at the central region of the capsid, with a single loosely-packed dsRNA molecule (~ 20 bp/100 nm³, with an interstrand spacing of ~ 40 –45 Å in the case of chrysovirus and partitivirus). A similar value for packed dsRNA, 25 bp/100 nm³, if there is one dsRNA molecule in the capsid, was proposed for quadriviruses. Such low density at the central region of the capsid may increase dsRNA mobility, which might be necessary for maximum RdRp activity with the RdRp complex. Interestingly, the amount of dsRNA1 and dsRNA4 in the quadrivirus virions were consistently less than those of dsRNA2 and dsRNA3 (Fig. 3(b)), and a similar proportion of the virion dsRNA profile was observed in a chrysovirus, *Helminthosporium victoriae* virus 145S (HvV145S, a proposed genus *Alphachrysovirus*, formerly the genus *Chrysovirus*). Thus, it is also tempting to speculate that two heterogeneous dsRNA sets, dsRNA1 + dsRNA4 (8.6 kbp total) and dsRNA2 + dsRNA3 (8.5 kbp total), where each set always shows a similar accumulation ratio, are separately packed in the two different capsids. If this is the case, an alternative density for the quadrivirus capsid with two

Fig. 3 Quadrivirus dsRNA and protein components. (a) SDS-PAGE pattern of structural proteins of RnQV1-W1118 and -W1075. (b) Agarose gel electrophoresis of RnQV1-W1118 and -W1075 genomic dsRNA segments. The genomic dsRNA segments of a mycoreovirus (MyRV1 S1–S6, and others are not shown) and a DNA size marker (M) were used as size standards. Reproduced from Fig. 1(b) and (c) of Lin, Y.H., Hisano, S., Yaegashi, H., Kanematsu, S., Suzuki, N., 2013. A second quadrivirus strain from the phytopathogenic filamentous fungus *Rosellinia necatrix*. *Archives of Virology* 158, 1093–1098, with permission from Springer.

heterologous dsRNA molecules could conceivably be calculated as 50 bp/100 nm³. See the other article of this section “Structure of Double-Stranded RNA Mycoviruses” by Castón *et al.* for further discussion of this possibility.

Genome Organization and Expression

Quadriviruses have a multi-segmented genome consisting of four monocistronic linear dsRNA segments. The complete genome sequence of the RnQV1-W1075 isolate is a total of 17,078 bp. Each dsRNA segment ranges from 3.7 to 4.9 kbp (GC contents are 51.9%–54.3%) and has a single large open reading frame (ORF) covering 86%–97% of its segment size (Fig. 4). The largest segment, dsRNA1 (4942 bp), codes for a protein of unknown function (P1, 1602 amino acid residues, 178.2 kDa). The third segment, dsRNA3 (4099 bp) codes for RdRp (P3, 1310 amino acids, 146.8 kDa). The second and fourth segments, dsRNA2 (4352 bp) and dsRNA4 (3685 bp) code for the two structural proteins, P2 (1356 amino acids, 147.4 kDa) and P4 (1061 amino acids, 113.2 kDa), respectively. The quadripartite nature of quadriviruses resembles that of the traditional chrysoviruses including several members of the proposed genus Alphachrysovirus and alternaviruses members of the proposed family Alternaviridae. However, the total size of quadrivirus genome (3.7–4.9 kbp, 17.1 kbp total) is approximately 1.5–1.7 fold larger than those of traditional chrysoviruses (2.5–3.6 kbp, ~12.6 kbp total) and alternaviruses (1.4–3.6 kbp, 10.4 kbp total).

The 5'- and 3'-terminal nucleotide sequences of the four dsRNA genome segments of RnQV1 are conserved (the positive-sense strand sequence of the RnQV1-W1075 is 5'-C/UACGAU-CAUGAGAAUUAUCG/A-3', Fig. 4). Several conserved sequence stretches are also present at both untranslated regions (UTRs), and the 3'-ends are better conserved than the 5'-end regions. The heterogeneity at the extreme termini, C or U for the 5'-end and G or A for 3'-end, is notable. As is found in typical chrysoviruses and some partitiviruses, “CAA” repeats were also found in the 5'-UTR, or within the adjacent coding region of each RnQV1 segment, except for dsRNA3. The (CAA) repeat sequences are known to serve as enhancer elements present at the 5'-UTRs of tobamoviruses, plant alpha-like viruses. Recently, the 5'-UTRs of two typical chrysoviruses, *Cryphonectria nitschkei* chrysovirus 1 and HvV145S (215 and 293 nt, respectively), were found to have internal ribosomal entry site (IRES) activities, while those of

Fig. 4 Genomic organization of RnQV1 isolate W1075. The genome consists of four monocistronic dsRNA segments. dsRNA3 encodes the putative replicase (RdRp), while dsRNA2 and dsRNA4 encode structural proteins. dsRNA1 encodes a putative non-structural protein with unknown function. The sequence stretches conserved among below the dsRNA4. Solid lines and colored open boxes represent genomic dsRNAs and open reading frames on the positive-sense strands, respectively.

quadriviruses are relatively short (23–45 nt) and contain no IRES activity. The translation significance of (CAA)_n in translation may differ between quadriviruses and chrysovirus. Alternaviruses and members of genera *Alphapartitivirus* and *Betapartitivirus* have poly(A) tails or poly(A) tracts either at the 3'-terminus or near the 3'-terminus of the coding-strand, whereas quadriviruses and most other dsRNA viruses have no such poly (A) rich sequences.

Although little is known about the replication of multi-segmented dsRNA mycoviruses, their replication and transcription appear to occur inside particles involving virion-associated RdRps, similar to other well studied dsRNA viruses such as rice dwarf virus (a plant reovirus, genus *Phytoreovirus*, family *Reoviridae*) and yeast L-A virus (*Saccharomyces cerevisiae* virus L-A, genus *Totivirus*, family *Totiviridae*). Therefore, RnQV1 P3 (RdRp) may be involved in the genomic dsRNA replication and transcription, although the presence of RdRp in the quadrivirus virions remains to be confirmed. The putative small pores are located at the five-fold (~11 Å-diameter hole) and three-fold axes (~7 Å-diameter hole) of the RnQV1 capsid. This feature resembles that of other single-shelled *T* = 1 capsids of dsRNA mycoviruses, suggesting that the conformational changes in P2 and/or P4 that face the channel wall might allow the exit of viral transcripts. In addition, the presence of two putative insertion sites in the P2 and P4 proteins, which allocate the virus capsid outer surface, is hypothesized to possess enzyme activities. Interestingly, in the case of the yeast L-A virus capsid, the inserted domain is located at a trench on the outer surface and can be responsible for catalyzing the unique “cap-snatching” reaction, which is known as an alternative method for capping mRNA.

Molecular and Biological Properties

The three RnQV1 isolates were found in *R. necatrix* strains W1075, W1118 and W726 were obtained from the Japanese pear orchards in the Saga, Ibaraki, and Saga Prefectures of Japan. RnQV1-W1075 and W1118 have been completely sequenced, while only the complete sequence of dsRNA3 is available for RnQV1-W726. Nucleotide sequence identities between RnQV1-W1075 and W1118 vary from 67% (dsRNA1 and dsRNA3) to 70% (dsRNA2). Amino acid sequences identities between two virus isolates showed 72% (P1), 81% (P2), 74% (P3) and 82% (P4). The W726 dsRNA3 (RdRp) shows 86% and 66% nucleotide sequence (98% and 75% amino acid sequence) identities to that of W1075 and W1118, respectively. Rabbit polyclonal antibodies against RnQV1-W1075 P2 recognize RnQV1-W1118 P2 by western blot analysis. Since a number of field isolates displayed similar dsRNA profiles to that of quadriviruses, it seems that quadriviruses are widespread in the *R. necatrix* population.

The RnQV1 persistently infects its natural fungal host *R. necatrix* and is transmitted intracellularly during cell division and/or mycelial cell fusion (hyphal anastomosis). Transfection of protoplasts from *R. necatrix* and *Cryphonectria parasitica* (an experimental model fungal host) by purified RnQV1 particles was unsuccessful. Little is known about the virus vertical transmission during sexual or asexual sporulation, or about extracellular transmission in nature. The RnQV1 is stably maintained in the host fungus during successive subcultures for a long period of time. However, viral infection has no discernible phenotypic effects on their host colony morphology, suggesting it is a symptomless infection. The spread of RnQV1 throughout the fungal colonies is relatively slower than other *R. necatrix*-infecting viruses, such as Rosellinia necatrix megabirnavirus 1 and Rosellinia necatrix partitivirus 1, because its dsRNA distribution within a colony is uneven, forming sectors with low levels of virus accumulation. RnQV1 does not block transgene silencing, and thus, it appears to have no RNA silencing suppressor activity. RnQV1 does not upregulate antiviral RNA silencing-related genes, while some other viruses do in *R. necatrix*. Next-generation sequencing analyses suggested that sense-strand-specific viral small RNA peaks were found at the 3' termini of RnQV1 segments. Nevertheless, the

Fig. 5 Phylogenetic relationships of RnQV1 and other related dsRNA viruses. A neighbor-joining tree was constructed from the amino acid sequences alignment based on the RdRp proteins of quadriviruses and selected dsRNA viruses including totiviruses, chrysovirus and botybinaviruses. Numbers at the nodes represent bootstrap percentages (1000 replicates). The scale bar represents the amino acid distances.

abundance of RnQV1 small RNAs was significantly lower than those of other studied *R. necatrix* dsRNA viruses, suggesting that RnQV1 is sequestered from the RNA silencing machinery, or that it has unknown counter-defense mechanism(s).

Phylogenetic and Evolutionary Relationships of RnQV1 to Other dsRNA Mycoviruses

Virus-like dsRNA elements, namely Amasya cherry disease (ACD)-associated dsRNAs with sequence similarity to RnQV1 dsRNA segments together with two novel mycoviruses (chrysovirus and partitivirus), were identified from diseased cherry trees. RnQV1 P3 shows moderate levels of amino acid sequence identities to polypeptides encoded by ACD large (L) dsRNA3 (35%) and L dsRNA4 (36%), which putatively encode RdRps that are related to each other, and are clustered together with quadriviruses in the

phylogenetic tree (Fig. 5). RnQV1 P1 shows weak amino acid sequence identities to polypeptides encoded by ACD L dsRNA1 (19%) and L dsRNA2 (27%). Although no ACD-associated dsRNA segments encoding structural proteins similar to RnQV1 P2 (dsRNA2) and P4 (dsRNA4) have been detected, it might be that these quadrivirus-like dsRNAs are derived from two related mycoviruses. Similarly, quadrivirus-like dsRNA elements, together with two other mycoviruses, were also isolated from the cherry leaves that had Cherry chlorotic rusty spot disease (CCRS). The etiology of ACD and CCRS occurring in Turkey and Italy, respectively, is still unknown. However, a Spanish fungal disease called Cherry leaf scorch (CLS), that has very similar symptoms to CCRS and mycovirus-like dsRNA-elements, is suggested to be caused by *Apiognomonia erythrostoma* (class Sordariomycetes). Thus, ACD- and CCRS-associated dsRNAs are likely of a fungal virus origin.

RnQV1 P3 shows 22%–33% amino acid sequence identities to RdRps of other dsRNA mycoviruses, including the members of the families *Totiviridae* (unsegmented dsRNA genome) and *Chrysoviridae* (multi-segmented dsRNA genome). Phylogenetic analyses show that quadriviruses are more closely related to members of the family *Totiviridae* than to other known quadripartite dsRNA viruses, such as chrysovirus and alternaviruses (Fig. 5, alternaviruses are not included). Quadriviruses and members of the genus *Totivirus* that have unsegmented genomes with two large ORFs for a capsid protein and a RdRp, form a well-supported monophyletic cluster within the *Totiviridae* family clade, suggesting that they descended from a common ancestor except for a unique totivirus, *Ustilago maydis* virus H1 (UmV-H1), that has a single ORF encoding a polypeptide with a capsid protein and RdRp domains. UmV-H1 and yeast L-A totivirus commonly have additional components (i.e., satellite dsRNAs), which encode secreted toxin precursor proteins responsible for the killer phenomena. UmV-H1 is phylogenetically related to recently discovered unsegmented dsRNA mycoviruses (relatives of UmV-H1) and botybirnaviruses (two-segmented dsRNA genome) (Fig. 5). Therefore, it is necessary to revise the taxonomy of the current members of the *Totivirus* genus based on phylogenetic relationships. Similar to quadriviruses, the betachrysovirus and botybirnavirus capsid may be composed of two different structural proteins. In addition, some plant-infecting deltapartitiviruses may have three dsRNA genome segments and encode two different structural proteins. The acquisition of two different structural protein genes (quadriviruses and probably betachrysoviruses), the duplication of a structural protein gene (botybirnaviruses and presumably some tripartite partitiviruses) and the duplication of a helix-rich domain within one single gene (alphachrysoviruses) possibly occurred independently during the course of evolution of these dsRNA mycoviruses.

At the time of writing this article, a new quadrivirus, designated as *Leptosphaeria biglobosa* quadrivirus 1, with a quadripartite dsRNA genome, was reported from the blackleg disease fungus *Leptosphaeria maculans* (anamorph *Phoma lingam*, class *Dothideomycetes*) infecting oilseed rape (*Brassica napus*). This virus shares many molecular characteristics with RnQV1, but its RdRp is more closely related to the putative RdRps encoded by ACD L dsRNA3 and dsRNA4, and CCRS L dsRNA3 and dsRNA4.

This is an update of S.A. Ghabrial, Totiviruses, In Encyclopedia of Virology (Third Edition), edited by Brian W.J. Mahy and Marc H.V. Van Regenmortel, Elsevier Ltd., 2008, doi:10.1016/B978-012374410-4.00518-5.

Glossary

Anastomosis Fusion between hyphal branches allowing for exchange of cytoplasm, ions, and organelles, and the most common means of horizontal transmission of mycoviruses.

Conidia Asexual, non-motile fungal spores.

Mycoviruses Viruses that infect and multiply in fungi.

Protoplast A cell that has its cell wall removed, allowing for membrane fusion.

Pseudoknot A secondary structure in viral mRNA that slows movement of the ribosome and may cause a frameshift that allows entry to an alternative reading frame during translation.

Ribosomal frameshifting Ribosomes switching reading frame on an mRNA, in response to the presence of a slippery site and/or a pseudoknot, to synthesize a fusion protein or a polyprotein from two overlapping reading frames.

RNA silencing The negative regulation or inhibition of gene expression by non-coding RNA elements, also called RNA interference (RNAi).

Totivirids Viruses within the family *Totiviridae*.

Totiviruses Viruses within the genus *Totivirus*.

Vegetative incompatibility Genetic differences between fusing vegetative hyphae of fungi that result in unviable heterokaryons and prevent horizontal mycovirus transmission.

Introduction

The discovery of the killer phenomenon in the 1960s in yeast (*Saccharomyces cerevisiae*) and in the smut fungus (*Ustilago maydis*) eventually led to the discovery of the isometric double-stranded (ds) RNA mycoviruses with nonsegmented genomes, currently classified in the genus *Totivirus* (family *Totiviridae*), distinguishing them by that name from the partitiviruses, which had segmented genomes. An interesting feature of these viruses became apparent: virus-infected killer strains of yeast or smut secrete a protein toxin to which they are immune, but which is lethal to sensitive cells. The precursor to the killer toxin is now known to be encoded by a satellite dsRNA, which is dependent on a helper totivirus for encapsidation and replication.

Unlike the totiviruses associated with the yeast and smut killer systems, other members of the family *Totiviridae* are not known to be associated with killer phenotypes. The other accepted genera in the family *Totiviridae* include the viruses that infect filamentous fungi (members of the genus *Victorivirus*) and those that infect parasitic protozoa (members of the genera *Giardiavirus*, *Leishmaniavirus*, and *Trichomonasvirus*). Genera proposed to be included in the family *Totiviridae* include *Artivirus* and *Eimeriavirus*, neither of which contain toxin-producing member viruses. The viruses constituting the family *Totiviridae*, including proposed members, will be referred to here as totivirids, distinguishing them from members of the genus totivirus.

Totivirids that infect fungi and protozoa were the first dsRNA viruses with undivided genomes. The new dsRNA virus family *Amalgaviridae* also has undivided genomes with an architecture similar to members of the *Totiviridae*, but they are phylogenetically more closely related to the *Partitiviridae* family of viruses. Purified preparations of some of several totivirids and similar viruses contain dsRNA species suspected of being satellite or defective dsRNAs. An extreme example of this phenomenon is the relationship between yado-nushi virus 1 (YnV1), an unclassified totivirus most closely related to members of the genus *Giardiavirus*, which hosts and encapsidates a viral RNA, yado-kari virus 1 (YkV1), that is most closely related to members of the positive-sense (+)RNA virus family *Caliciviridae*.

The realization by the scientific community of the breadth of the family *Totiviridae* is leading to broader interest in these viruses among virologists. Further spurring this interest is the realization that several of these viruses have measurable effects on hosts of economic importance, including reduction of virulence or fitness in filamentous fungi, disease in crustaceans and fish, and enhanced virulence in protozoans that cause human disease. As a group, the totivirids constitute a rapidly expanding family, with metagenomic information revealing new members on a continual basis. In many instances, host-virus relationships are unknown, but the growing set of tools available for study is demonstrating the biological importance of these viruses.

In addition to examining the similarities and differences among members of the family *Totiviridae* (totivirids), this article will focus on the totivirids that infect filamentous fungi, a group of viruses that are phylogenetically more closely related to each other

¹Authors' note: This article is an update of the same chapter in the Third Edition written by Dr. Said A. Ghabrial. Dr. Ghabrial died before the rewrite of this article began, and thus was never able to have input into the content of the updated chapter. So even though roughly half of the content here is originally Dr. Ghabrial's, he is not listed as a co-author.

than to other totiviruses and utilize a different strategy to express their genomes. The yeast and smut totiviruses and associated killer systems, as well as the totivirids infecting parasitic protozoa, are discussed elsewhere in this encyclopedia.

Taxonomy of and Evolutionary Relationships Among Totivirids

The family *Totiviridae* currently accommodates five genera, *Giardiavirus*, *Leishmanivirus*, *Totivirus*, *Trichomonasvirus*, and *Victorivirus*. There are two additional proposed genera within the family, *Artivirus* and *Eimeriavirus*, which are not yet recognized by the International Committee on Taxonomy of Viruses (ICTV). The genus *Victorivirus*, derived from the specific epithet of *Helminthosporium victoriae*, was erected to accommodate HvV190S, and currently the largest in the family *Totiviridae*, with 14 ICTV-recognized members and many tentative victoriviruses that infect filamentous fungi. The members of one genus can be distinguished from those of another genus in genome expression strategy, phylogenetic relation, and/or natural host range (see below). The family encompasses a broad range of viruses characterized by isometric particles, ~40 nm in diameter, that contain a monosegmented dsRNA genome coding for a capsid protein (CP) and an RNA-dependent RNA polymerase (RdRp). Viruses within the *Totiviridae* are found in the major clade that contains most of the dsRNA viruses, including the largest dsRNA family, the *Reoviridae*. This branch that includes dsRNA viruses is thought to have arisen from the branch of (+)ssRNA viruses containing the alpha and flaviviruses, and the dsRNA branch in turn is hypothesized to have given rise to the negative-sense RNA viruses.

Sequence comparisons of the predicted amino acid sequences of totivirid RdRps indicate that they share significant sequence similarity and characteristically contain eight conserved motifs. This sequence similarity was common to all totivirids so far characterized including the totivirids that infect the yeast, smut, filamentous fungi, and plants as well as those infecting parasitic protozoa. It is notable that an expanded phylogenetic tree based on RdRp sequences of all dsRNA viruses makes it apparent that viruses currently contained within – or proposed to be contained within – the family *Totiviridae* does not form a monophyletic group. In particular, the genera *Victorivirus*, *Leishmanivirus*, *Trichomonasvirus*, and proposed genus *Eimeriavirus* consistently group together, but the genera *Totivirus* and *Giardiavirus* and the proposed genus *Artivirus* do not group with the others. Instead, each of those last three represents a separate small clade within the greater clade of dsRNA viruses related to the totivirids, with viruses representing families including the *Chrysoviridae* and *Quadriviridae*, as well as several clades not yet classified intercalated into that larger “Toti-Chryso” clade. These facts suggest the necessity of taxonomical reorganization of these members of the family *Totiviridae* and related viruses with a similar genome organization but different phylogenetic relationships.

Phylogenetic analysis based on multiple alignments of amino acid sequences of totivirids RdRp conserved motifs (Fig. 1) shows that the viruses infecting filamentous fungi (victoriviruses) are most closely related to each other and form a distinct large well-supported cluster (bootstrap value of 97%). Likewise, phylogenetic trees based on the CP sequences showed similar topology to those based on RdRp sequences, although in some cases with less support (Fig. 2). The leishmaniviruses LRV1, LRV2, and LRV4 (percent sequence identities of 46%) are most closely related to each other and form a discrete cluster with 100% bootstrap value. This is also true for the two yeast viruses ScV-L-A and ScV-LBC (RdRp identity of 32%), members of the genus *Totivirus*. UmV-H1, the third member in the genus *Totivirus* forms a phylogenetic clade distinct from the cluster of the two yeast totiviruses. This may reflect the difference in RdRp expression strategy between these viruses (see below). It is of interest that HvV190S and related victoriviruses are phylogenetically more closely to the protozoan-infecting members of the *Totiviridae*, including trichomonasviruses, leishmaniviruses, and the proposed genus *Eimeriavirus*, typified by the unclassified *Eimeria brunetti* RNA virus 1 (EbrV-1), which infects an apicomplexan parasitic protozoan, than to the yeast viruses (Figs. 1 and 2). It was previously hypothesized that leishmaniviruses and the fungal totivirids are of old origin having existed in a single-cell-type progenitor prior to the divergence of fungi and protozoa. The closer relationship of victoriviruses to protozoal viruses than to yeast viruses in the genus *Totivirus* is consistent with this idea.

Virion Properties

The buoyant densities in CsCl of virions of members of the family *Totiviridae* range from 1.36 to 1.43 g cm⁻³, and the sedimentation coefficients of these virions range from 160S to 190S (S20w, in Svedberg units). Particles lacking nucleic acid sediment with apparent sedimentation coefficients of 90–105S. Isolates of ScV-L-A and UmV-H1 may have additional components, containing satellite or defective dsRNAs, with different sedimentation coefficients and buoyant densities. Virion-associated RdRp activity can be detected in all totivirids examined to date. Protein kinase activity is associated with HvV190S virions; capsids contain phosphorylated forms of CP.

Virion Structure and Composition

The totivirids have isometric particles, approximately 40–50 nm in diameter, with icosahedral symmetry (Fig. 3). The capsids are single-shelled and are composed of a single major polypeptide. The capsids consist of 120 CP subunits of molecular mass in the range of 76–98 kDa. The capsid structures of six members or tentative members of the family *Totiviridae* have been determined

Fig. 1 Maximum Likelihood (ML) phylogenetic tree constructed based on the RNA-dependent RNA polymerase (RdRp) sequences of selected members and proposed member of the family *Totiviridae*. Not all family members were included for space considerations, but the overall topology of the tree generally reflects the topology of the tree when all available sequences were included. A single member of the family *Quadriviridae* and the family *Chrysoviriidae* was included to indicate positions within the larger clade that currently constitutes the family *Totiviridae*. The RdRp sequences were derived from aligned deduced amino acid sequences of members of the family *Totiviridae* using the program MUSCLE. The phylogenetic tree was generated using the program IQ-TREE with 1000 ultrafast bootstrap replicates. A VT + F + I + G4 model of evolution was selected based on Akaike and Bayesian information criteria. Bootstrap support above 70% are indicated on branches.

using cryo-transmission electron microscopy combined with three-dimensional image reconstruction (Fig. 4). In all cases, the capsids of the fungal totivirids are made up of 60 asymmetric CP dimers arranged in a so-called 'T=2' layer, equivalent to a T=1 structure in which the structural units are homodimers rather than monomers. There are structural differences among the viruses examined to date. Surface differences of particles are apparent across the family. Compared to the yeast L-A capsid, the HvV190S capsid shows relatively smoother outer surfaces, but both are more apparently icosahedral, while the trichomonasvirus TVV1, giardiavirus GLV, and proposed artiviruses OmRV and IMNV are more apparently spherical in cryoEM reconstructions. IMNV has an overall shape like OmRV, but it uniquely has fiber protrusions at the pentamers. The quaternary organization of the HvV190S particle is notably similar to that of yeast L-A and the cores of the larger dsRNA viruses of plants and animals: the A-subunits cluster around the fivefold axis and B-subunits around the threefold axis.

The ScV-L-A CP removes the 5' cap structure of host mRNA and covalently attaches it to the histidine residue at position 154. The decapping activity is required for efficient translation of viral RNA. The published yeast L-A capsid structure reveals a trench at the active site of decapping.

Like other totivirids, a single gene encodes the capsid of HvV190S, but the HvV190S capsid comprises two closely related major CPs, either p88 and p83 or p88 and p78. The capsids of all other totivirids so far characterized appear to contain only a single major CP. Interestingly, HmTV-1-17, a totivirid infecting a filamentous fungus, has similar capsid heterogeneity to that of HvV190S. Purified HvV190S virion preparations contain two types of particles, 190S-1 and 190S-2, which differ slightly in sedimentation rates (190S-1 is resolved as a shoulder on the slightly faster sedimenting component 190S-2) and capsid

Fig. 2 Maximum Likelihood phylogenetic tree constructed based on the capsid protein (CP) sequences of selected members and proposed member of the family Totiviridae. The viruses and strains selected and the methods used were the same as those used in Fig. 7. A VT + F + G4 model of evolution was selected based on Akaike and Bayesian information criteria.

composition. The 190S-1 and 190S-2 virions are believed to represent different stages in the virus life cycle. The 190S-1 capsids contain p88 and p83, occurring in approximately equimolar amounts, and the 190S-2 capsids comprise similar amounts of p88 and p78. p88 and p83 are phosphoproteins, whereas p78 is nonphosphorylated (Fig. 5). Totivirid virions encapsidate a single molecule of dsRNA, 4.6–7.0 kbp, with tentative members of the family ranging up to 7.8 kbp. Some totivirids may additionally contain satellite dsRNAs or defective dsRNAs, which are encapsidated separately in capsids encoded by the totivirid genome.

Genome Organization and Expression

In general, the genome organization of the totivirids infecting fungi and other eukaryotes are similar: each virus genome contains two large open reading frames (ORFs); the 5' proximal ORF encodes a CP and the 3' ORF encodes an RdRp (Fig. 6).

Two distinct RdRp expression strategies have been reported for viruses in the family Totiviridae: those that express RdRp as a fusion protein (CP–RdRp) by ribosomal frameshifting, such as *Saccharomyces cerevisiae* virus L-A and the viruses that infect parasitic protozoa; and those that synthesize RdRp as a separate nonfused protein by an internal initiation mechanism, as shown for HvV190S and proposed for all of the other totivirids that infect filamentous fungi. An exception to this rule is *Ustilago maydis* virus H1 (Umv-H1), currently being classified into the genus Totivirus. The Umv-H1 genome contains only a single ORF that encodes a polyprotein, predicted to be autocatalytically processed by a viral papain-like protease to generate the CP and RdRp proteins.

In most *Giardiavirus*, *Totivirus*, and proposed *Artivirus* members, a –1 frameshift regulates translation between the two main ORFs; in members of *Trichomonasvirus* a –2 frameshift regulates translation, and in *Leishmanivirus* a +1 frameshift regulates translation between the two main ORFs. In each of these cases, a fusion protein consisting of the CP and RdRp occasionally results, and that fusion product is incorporated in virions. In most members of the genus *Victorivirus*, a translational stop-start separates the two main ORFs, with the termination codon of the CP ORF overlapping the initiation codon of the RdRp ORF in the tetranucleotide sequence AUGA or UAAUG. Other translational details in members or proposed members of the family Totiviridae

Fig. 3 Negative contrast electron micrograph of particles of an isolate of *Helminthosporium victoriae* 190SV, the type species of the genus Victorivirus. Scale = 50 nm. Reprinted from Ghabrial, S.A., 2008. Totiviruses. In: Mahy, B.W.J., Van Regenmortel, M.H.V. (Eds.), Encyclopedia of Virology (Third Edition), New York: Academic Press, pp. 163–174.

Fig. 4 Structural comparison of totivirid, OmRV, and other totivirus-related viruses. Electron density volume map of Omono River virus (OmRV, 8.3 Å resolution), infectious myonecrosis virus (IMNV, 8.0 Å resolution), *Saccharomyces cerevisiae* virus L-A (ScV-L-A, 8.5 Å resolution), *Helminthosporium victoriae* virus 190S (HvV190S, EMD Accession code: 5726, 7.5 Å resolution), *Trichomonas vaginalis* virus 1 (TVV1, EMD Accession code: 2184, 6.7 Å resolution), and *Giardia lamblia* virus (GLV, EMD Accession code: 5948, 6.0 Å resolution). The 8.5 Å electron density volume map of ScV-L-A was generated from the crystallographic capsid model (PDB ID: 1M1C) using Chimera60. The surface of the structures was colored according to the distance from the center of the virion (green < 131 Å, yellow < 193 Å, red < 220 Å, light blue < 250 Å, blue < 280 Å). Reprinted from Okamoto, K., Miyazaki, N., Larsson, D.S.D., *et al.*, 2016. The infectious particle of insect borne totivirus-like Omono River virus has raised ridges and lacks fiber complexes. Springer. Scientific Reports 6, 1–14.

may include additional small ORFs, additional protease cleavage sites, 2A-like and pseudo 2A-like sequences, and pseudoknot sequences that facilitate frameshifting.

The totivirids express their RdRps either as CP–RdRp (gag-pol-like) fusion proteins or as separate nonfused proteins. Expression of RdRp as a CP–RdRp fusion protein via -1 ribosomal frameshifting has been well documented for ScV-L-A. Virion-associated CP–RdRp has been detected as a minor protein in the capsids of ScV-L-A, ScV-L-BC, TVV, and GLV. Expression of RdRp as a fusion protein in LRV1-1, LRV1-4, or LRV2-1 by $+1$ ribosomal frameshifting or ribosomal hopping has been proposed.

The overlap region between ORF1 and ORF2 of ScV-L-A (130 nt), LRV1-1 and LRV1-4 (71 nt), and GLV (122 nt) contains the structures necessary for ribosomal frameshifting including a slippery site and a pseudoknot structure to promote fusion of ORF1 and ORF2 *in vivo*. Although the overlap region in TVV is short (14 nt), it contains a potential ribosomal slippage heptamer.

There is currently no evidence for CP–RdRp fusion proteins in HvV190S or other victoriviruses. The overlapping region in the dsRNA genomes of HvV190S is AUGA, where the initiation codon of the RdRp ORF overlaps the termination codon of the CP ORF, suggesting

Fig. 5 Sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) analysis of HvV190S sedimenting components 190S-1 and 190S-2. Purified preparations of HvV190S contain two types of particles, 190S-1 and 190S-2, which differ slightly in sedimentation rates. The 190S-1 capsids contain p88 and p83, occurring in approximately equimolar amounts, and the 190S-2 capsids comprise similar amounts of p88 and p78. The capsid proteins p88 and p83 are phosphorylated, whereas p78 is nonphosphorylated. Reprinted from Ghabrial, S.A., 2008. Totiviruses. In: Mahy, B.W.J., Van Regenmortel, M.H.V. (Eds.), Encyclopedia of Virology (Third Edition), New York: Academic Press, pp. 163–174.

Fig. 6 Genome organizations of selected members and proposed members of the family Totiviridae. The dsRNA genome encompasses two large open reading frames (ORFs) with the 5' ORF encoding a capsid protein (CP) and the 3' ORF encoding an RNA-dependent RNA polymerase (RdRp). Details are described in the text. Except for the members of the genus *Victorivirus*, translation of the RdRp ORF proceeds as a consequence of a frameshift from the CP ORF, resulting in a CP-RdRp fusion protein that is a component of the capsid. Translation of the RdRp of members of the genus *Victorivirus* proceeds by internal ribosome initiation following termination of translation of the CP sequence at a translational stop-start site.

that expression of RdRp occurs by a mechanism different from translational frameshifting. For HvV190S, the stop codon of the CP ORF (nucleotide position 2606-UGA-2608) overlaps with the start codon (nucleotide position 2605-AUG-2607) for the RdRp ORF in the sequence AUGA. Other victoriviruses have either the pentanucleotide UAAUG or, in the case of *Alternaria alternata* victorivirus 1 (AaVV1), a putative –1 frameshift. But in none of these instances has a CP-RdRp fusion protein been identified in translation experiments or in virus particles; rather, each appears to represent a slightly different mechanism for termination of the CP and initiation of the RdRp.

The 5' end of the plus strand of all totivirids dsRNAs examined to date is uncapped and the 3' end is not polyadenylated. As noted, ScV-L-A uses a cap-snatching mechanism to provide capped mRNAs for efficient translation. The 5' end of HvV190S dsRNA is uncapped and highly structured and contains a relatively long (289 nucleotides) 5' leader with two minicistrons. These structural features of the 5' untranslated region (UTR) of HvV190S dsRNA suggest that the CP-encoding ORF1 (with its AUG present in suboptimal context according to the Kozak criteria) is translated via a cap-independent mechanism. The 5'-UTR of the leishmanivirus LRV-1-1 functions as an internal ribosome entry site (IRES). Translation of the uncapped giardiavirus GLV mRNA in *Giardia lamblia* is initiated on a unique IRES element that contains sequences from a part of the 5'-UTR and a portion of the capsid coding region. IRES activities are also observed in the 5'-UTR of the victoriviruses HvV190S and *Rosellinia necatrix* victorivirus 1.

The UGA codon at position 2606–2608 of the HvV190S genomic plus strand was verified by site-directed mutagenesis to be the authentic stop codon for ORF1. The RdRp-encoding downstream ORF2 of HvV190S is in a –1 frame with respect to ORF1 and is expressed via an internal initiation mechanism (a coupled termination–initiation mechanism is proposed). The HvV190S RdRp is detectable as a separate, virion-associated component, consistent with its independent translation from ORF2.

The viral genome of IMNV, a monosegmented dsRNA virus infecting penaeid shrimp and tentatively assigned to the family *Totiviridae* in the proposed genus *Artivirus*, encompasses two nonoverlapping ORFs with ORF1 encoding a polyprotein comprised of a putative RNA-binding protein and a CP. The coding region of the RNA-binding protein is located in the first half of ORF1 and contains a dsRNA-binding motif in the first 60 amino acids. The second half of ORF1 encodes a CP, as determined by amino acid sequencing, with a molecular mass of 99 kDa. ORF2 encoded a putative RdRp with the eight conserved motifs characteristic of totivirids. Phylogenetic analysis based on the RdRp clustered IMNV with other invertebrate-infecting members in the family *Totiviridae* and separate from the five established genera. Important novel features of the genome organization of IMNV have significant bearing on how the viral proteins are expressed, and these features appear to be shared among closely related viruses and are continuing to evolve. These features include two encoded '2A-like' motifs, which are likely involved in ORF1 polyprotein 'cleavage', a 199 nt overlap between ORF1 and ORF2, and the presence a 'slippery heptamer' motif and predicted RNA pseudoknot in the region of ORF1–ORF2 overlap. The latter features probably allow ORF2 to be translated as a fusion with ORF1 by –1' ribosomal frameshifting. The generation of CP as a polyprotein and the potential involvement of the IMNV-encoded '2A-like' peptides (GDVESNPGP and GDVEENPGP) in processing of the polyprotein to release the major CP represent novel features that are not shared by closely related viruses in the proposed *Artivirus* genus of totivirids. Interestingly, more divergent viruses are predicted to have "pseudo 2A" sequences that could give rise to functional "2A-like" peptides by random mutation. In contrast, the potential expression of RdRp as a CP–RdRp fusion protein via ribosomal frameshifting is a common strategy utilized by other totivirids for expressing their RdRps.

Virus Replication Cycle

The replication cycle of totivirids has mainly been derived from in vitro studies of virion-associated RNA polymerase activity and the isolation of particles representing various stages in the replication cycle. In in vitro reactions, the RNA polymerase activity associated with virions of the fungal totivirids ScV-L-A, UmV-H1, and HvV190S, isolated from lag-phase cultures, catalyzes end-to-end transcription of dsRNA, by a conservative mechanism, to produce mRNA for CP, which is released from the particles. Purified ScV-L-A virions, isolated from log-phase cells, contain a less-dense class of particles, which package only plus-strand RNA. In in vitro reactions, these particles exhibit a replicase activity that catalyzes the synthesis of minus-strand RNA to form dsRNA. The resultant mature particles, which attain the same density as that of the dsRNA-containing virions isolated from the cells, are capable of synthesizing and releasing plus-strand RNA.

A proposed life cycle of HvV190S is depicted in [Fig. 7](#). Host-encoded protein kinase and protease have been shown to be involved in post-translational modification of CP. Phosphorylation and proteolytic processing are proposed to play a role in the virus life cycle; phosphorylation of CP may be necessary for its interaction with viral nucleic acid and/or phosphorylation may regulate dsRNA transcription/replication. Proteolytic processing and cleavage of a C-terminal peptide, which leads to dephosphorylation and the conversion of p88 to p78, may play a role in the release of the plus-strand RNA transcripts from virions ([Fig. 7](#)).

Biological Properties

The overall host range of the *Totiviridae*, including proposed members, includes an increasing breadth of eukaryotes. In addition to fungal and protozoal hosts, totivirids have been isolated from oomycetes, plants, insects, crustaceans, fish, and bats. The first such virus identified was a nonsegmented dsRNA virus with isometric particles, designated penaeid shrimp infectious myonecrosis virus (IMNV), isolated from diseased penaeid shrimp and tentatively assigned to the family *Totiviridae*. IMNV is the causal agent of the shrimp myonecrosis disease characterized by necrosis of skeletal muscle, particularly in the distal abdominal segments and tail fan. Phylogenetic analysis based on the RdRp region of viruses in the family *Totiviridae* suggests that *Giardia lamblia* virus (GLV; genus *Giardiavirus*) is the closest relative to IMNV. Related viruses infecting fish, insects, and bats cluster together phylogenetically and are proposed to constitute a new genus, *Artivirus*, which is not yet recognized by the International Committee on Taxonomy of Viruses (ICTV). The complete nucleotide sequences of many members and tentative members of the family *Totiviridae* have now been described.

There are no known natural vectors for the transmission of the fungal totivirids. They are transmitted intracellularly during cell division, sporogenesis, and cell fusion. Although the yeast totiviruses are effectively transmitted via ascospores, the victoriviruses infecting the ascomycetous filamentous fungi are essentially eliminated during ascospore formation. The leishmaniviruses and trichomonasviruses are propagated during cell division and are not infectious as purified virions. Members of the genera *Giardiavirus*, *Totivirus*, *Victorivirus*, and the proposed genus *Artivirus* such as IMNV, on the other hand, are infectious as purified virions. Successful transfection of the protozoan *Giardia lamblia* has also been accomplished via electroporation with plus-strand RNA transcribed in vitro from GLV dsRNA. Whereas IMNV causes a myonecrosis disease in its crustacean host, GLV is associated with latent infection of its flagellated protozoan human parasite *G. lamblia*. GLV is released into the medium without lysing the host cells and the extruded virus can infect many virus-free isolates of the protozoan host.

There is limited information on experimental host ranges for the fungal totivirids because infectivity as particles has been demonstrated for only a few. As a consequence of their intracellular modes of transmission, the natural host ranges of fungal totivirids are limited to individuals within the same or closely related vegetative compatibility groups, but particle-based and RNA-based infectivity systems are allowing for broader host range studies. Furthermore, mixed infections with two or more unrelated viruses are

Fig. 7 Life cycle of HvV190S. Mature virions contain a single dsRNA molecule and their capsids are composed entirely or primarily of the capsid protein (CP) p88. Virions representing different stages of the virus life cycle can be purified from the infected fungal host *Helminthosporium victoriae* including the well-characterized 190S-1 and 190S-2 virions. These two types of virions differ in sedimentation rate, phosphorylation state, and CP composition; 190S-1 capsids contain p88 and p83, whereas the 190S-2 capsids contain p88 and p78 (p88 is the primary translation product of the CP gene; p83 and p78 represent post-translational proteolytic processing products of p88 at its C-terminus). p88 and p83 are phosphorylated, whereas p78 is nonphosphorylated. The virions with phosphorylated CPs (p88 + p83) have significantly higher transcriptase activity *in vitro* than those containing the nonphosphorylated p78. Transcription occurs conservatively and the newly synthesized plus-strand RNA is released from the virions. Phosphorylation of CP is catalyzed by a host kinase, and is proposed to play a regulatory role in transcription/replication. A host-encoded protease catalyzes the proteolytic processing of phosphorylated p88; this occurs in two steps, leading first to p83 (the generation of the 190S-1 virions) and then to p78 (190S-2 virions). The conversion of p88-p83-p78 is proposed to play a role in the release of the plus-strand RNA transcripts from virions. The released plus-strand RNA is the RNA that is translated into CP and RNA-dependent RNA polymerase (RdRp) and packaged in capsids assembled from the primary translation product p88. It is not known whether p88 is phosphorylated before or after assembly. Synthesis of minus-strand RNA occurs on the plus-strand RNA template inside the virion; phosphorylation may be involved in turning on the replicase activity. Reprinted from Ghabrial, S.A., 2008. Totiviruses. In: Mahy, B.W.J., Van Regenmortel, M.H.V. (Eds.), *Encyclopedia of Virology* (Third Edition), New York: Academic Press, pp. 163–174.

common, probably as a consequence of the ways by which fungal viruses are transmitted in nature. Dual infection of yeast with ScV-L-A and ScV-L-BC and the filamentous fungus *Sphaeropsis sapinea* with SsRV-1 and SsRV-2 are examples of mixed infections involving totivirids. Dual infection of *H. victoriae* with the victorivirus HvV190S and the chrysovirus *Helminthosporium victoriae* virus 145 S (HvV145S) is an example of a mixed infection involving two unrelated viruses belonging to two different families.

The victorivirus from the phytopathogenic ascomycete fungus *Rosellinia necatrix*, *Rosellinia necatrix* victorivirus 1 (RnVV1), was eliminated from its host fungus by hyphal tipping and was reintroduced to its natural host and introduced to the fungus *Cryphonectria parasitica* by transfection. Negligible pathogenic effect was observed in either host. However, transfection of RnVV1 to an RNA silencing-deficient strain of *C. parasitica* revealed phenotypic effects of the virus in the RNA silencing-deficient strain, demonstrating that the virus is targeted by anti-viral RNA silencing in the fungus.

Many totivirids appear to be associated with symptomless infections of their hosts, but there is increasing evidence of biological impact of others. IMNV, an unclassified virus tentatively assigned to the proposed new genus Artivirus in the family Totiviridae, causes a myonecrosis disease in shrimp. The closely related Omono River virus isolated from *Culex* mosquitoes causes cytopathic effect in infected cells. Several recent studies suggest that members of the genera *Leishmanivirus* and *Trichomonasvirus* enhance their respective parasite-associated disease in humans by inducing proinflammatory responses at infection sites. These relationships are becoming recognized as increasingly important impacts of members of the family Totiviridae, and are covered in other chapters of this volume.

Multiple infections of totivirids with other totivirids or with unrelated viruses are common. In most instances, such mixed infections have not been dissected biologically. For example, a single isolate of *Trichomonas vaginalis* may be infected with all of the

Fig. 8 Colony morphology of virus-free and virus infected isolates B2 and A9, respectively, and three representative transfectants (B2-HvV190S-1, B2-HvV190S-2 and B2-HvV190S-3) of *Helminthosporium victoriae*. All fungal isolates were cultured on potato dextrose agar containing 0.5% (wt/vol) yeast extract medium. Reprinted from Xie, J., Havens, W.M., Lin, Y.-H., Suzuki, N., Ghabrial, S.A., 2016. The victorivirus *Helminthosporium victoriae* virus 190S is the primary cause of disease/hypovirulence in its natural host and a heterologous host. *Virus Research* 213, 238–245, Copyright (2015), with permission from Elsevier.

four known species of TVV. Mixed infections with HvV190S and HvV145S were initially associated with a debilitating disease of the fungal host. The two viruses are transmitted together via hyphal anastomosis and diseased isolates are characterized by reduced growth, excessive sectoring, aerial mycelial collapse, and generalized lysis. The disease phenotype of *H. victoriae*, the causal agent of Victoria blight of oats, is of special interest not only because diseased isolates are hypovirulent, but also because it was among the first examples of the viral etiology of hypovirulence of an important plant pathogen. It was only relatively recently that the role of the victorivirus HvV190S in the fungal disease was elucidated. Colonies regenerated from fungal protoplasts infected singly with HvV190S, but not HvV145S showed the disease phenotype (Fig. 8).

Virus–Host Relationships

The yeast killer system, comprised of a helper totivirus (ScV-L-A) and associated satellite dsRNA (*m*-dsRNA), is one of the few known examples where virus infection is beneficial to the host. The ability to produce killer toxins by yeast strains that in turn are immune to those toxins confers an ecological advantage over sensitive strains. The use of killer strains in the brewing industry provides protection against contamination with adventitious sensitive strains. Totiviruses maintain only the genes that are essential for their own survival (RdRp and CP), but killer viruses host accessory satellite segments that may be beneficial to their survival. The host cells have evolved to support only a defined level of virus replication, beyond which virus infection may become pathogenic. Because of amenability to genetic studies, the yeast–virus system has provided significant information on the host genes required to prevent viral cytopathology. Classical genetic studies with *S. cerevisiae* defined the first systems of chromosomal genes that regulate the copy number of a eukaryotic virus: the copy number of the totivirus ScV-L-A and its satellite M-dsRNAs were found to be downregulated by genes designated SKI (superkiller) or upregulated by genes designated MAK (maintenance of killer). More recently, the ecological flexibility of host/virus interactions in this system has been revealed: two host genes required for RNA silencing (Argonaute, AGO1, and Dicer, DCL1), and thus for interference with ScV-L-A multiplication, were found to be repeatedly gained or lost in different yeast strains, leading to the hypothesis that retaining these general virus resistance genes is more beneficial to the yeast in some circumstances, whereas eliminating these resistance genes and thus facilitating the presence of the killer viruses is more beneficial to the host in other circumstances.

While much less well-defined than the yeast system, the HvV190S victorivirus that infects the plant pathogenic fungus *H. victoriae* also utilizes host-encoded proteins, in this case a protein kinase and a protease for post-translational modification of its CP. Phosphorylation and proteolytic processing of CP may play a role in regulating transcription and the release of plus-strand transcripts from virions (Fig. 7).

The *H. victoriae*–virus system provides a well-studied and useful model system for examining virus–host interactions in a plant pathogenic fungus. A major attribute of this system is that the virus-infected *H. victoriae* isolates exhibit a disease phenotype

(Fig. 8). Furthermore, HvV190S can infect the heterologous fungal host *C. parasitica*, and also results in a disease phenotype in strains deficient in the RNA silencing pathway ($\Delta dcl-2$). It was previously demonstrated that the fungal gene Hv-p68, a novel alcohol oxidase/RNA-binding protein, is upregulated as a result of virus infection suggesting that upregulation of this gene might play a role in virus pathogenesis. Overexpression of Hv-p68 in virus-free fungal isolates, however, resulted in a significant increase in colony growth and did not induce a disease phenotype. Thus, overexpression of Hv-p68 per se is not sufficient to induce the disease phenotype in the absence of virus infection. Because dsRNA-binding proteins are known to sequester dsRNA and suppress antiviral host defense mechanisms, it is feasible that overexpression of the dsRNA-binding protein Hv-p68 may lead to the induction of the disease phenotype by suppressing host defense, but additional studies are needed to determine whether or not Hv-p68 upregulation has a role in viral pathogenesis.

Conclusions

Viruses in the family *Totiviridae* have common properties such as a two-ORF genome architecture and a T=1 capsid composed of 60 asymmetrical capsid protein dimers. Taxonomic considerations of totivirids have proceeded in large part by expanding the family *Totiviridae* to accommodate new genera as they are formally described. The family now contains five ICTV-approved genera and two tentative genera, among virus families with the most diverse host organisms. The genera are differentiated from one another in host range and gene expression. Elucidating the capsid structures of representatives of different genera and proposed genera of the family *Totiviridae* help to inform taxonomy of these viruses. More definitive information on variation in life cycles and genome expression strategies will also aid in putting this large and expanding family of viruses in taxonomic perspective. It is easy to envision a taxonomy in which the viruses considered here represent multiple families, but the utility for the community of virologists and biologists of such a restructuring would be needed, and perhaps should proceed only after the breadth of the family is better understood.

Glossary

2A-like motif A conserved self-processing peptide motif that cleaves a growing polypeptide chain co-translationally at a particular cleavage site. These motifs were first identified in members of *Picornaviridae*, separating structural proteins from replication-associated proteins. The motif is now known to be present in diverse RNA viruses.

Capsid protein The protective shell of viruses usually composed of multiple copies of same or different protein subunits for encasing viral genomes.

Mutualism Interspecific cooperation where two organisms belonging to two different species live together and benefit each other.

Trans-encapsidation or hetero-encapsidation Packaging of nucleic acid entities such as satellites by a capsid protein encoded by unrelated independent viruses.

Yado-kari In Japanese, it means borrowing a room in which to live or hermit crab biologically.

Yado-nushi In Japanese, it means someone who is the owner of the room.

Introduction

Typically, mycoviruses have either double-stranded (ds) or positive-sense single-stranded ((+)ss) RNA genomes. However, a few studies have also indicated the presence of mycoviruses with negative-sense (−) ssRNA genomes and geminivirus-like circular ssDNA genomes. Mixed mycovirus infections are common among fungi with occasional documented interplays between two unrelated viruses. Such virus-virus interactions can be categorized into three types: apparently neutral, synergistic and antagonistic. Synergistic interactions enhance the titer of one virus by another co-infecting virus, subsequently resulting in a different symptom expression than that induced in the host singly infected by either of the viruses. One such example is an enhancement of accumulation and vertical transmission of mycoreovirus 1 (MyRV1) in chestnut blight-causing fungus *Cryphonectria parasitica* by a co-infecting *Cryphonectria hypovirus* 1 (CHV1). In addition, in *Rosellinia necatrix*, *Rosellinia necatrix* megabarnavirus 2 (RnMBV2) reduces host virulence and growth only in the presence of *Rosellinia necatrix* partitivirus 1 (RnPV1). In return, RnMBV2 enhances accumulation of RnPV1 by two-fold. Individually, neither of the viruses causes any alterations to host virulence. In case of antagonistic interaction, one virus impairs the replication or accumulation of another co-infecting virus. For example, in *C. parasitica*, impairment of replication and lateral transmission of *Rosellinia necatrix* victorivirus 1 by either a co-infecting MyRV1 or a mutated CHV1 (lacking the RNA silencing suppressor). Replication impairment by MyRV1 is mediated by enhanced antiviral RNA silencing via transcriptional induction of its key genes namely dicer-like 2 (*DCL2*) and argonaute-like 2 (*AGL2*).

Recently, a unique mutualistic interplay between two RNA mycoviruses, Yado-nushi virus 1 (YnV1) and Yado-kari virus 1 (YkV1) has been described from a debilitated field isolate of *R. necatrix* strain W1032 from Nagano Prefecture, Japan. YnV1, an independent genuine double-stranded RNA (dsRNA) virus, trans-encapsidates the replicative-form dsRNA of the capsidless YkV1 (+)ssRNA (genomic RNA) along with its RNA-dependent RNA polymerase (RdRp), and is thereby responsible for YkV1 replication inside the host. In this way, despite being a (+)ssRNA virus, YkV1 likely replicates inside the hetero-capsid (particles) comprised of YnV1 capsid protein like a dsRNA virus. In return, YkV1 trans-enhances the accumulation of YnV1 by two- to four-fold, making the relationship rather mutualistic than commensal. This unique mutualistic interaction is different than the aforementioned virus-virus synergistic interactions, where two bona fide viruses (with the ability to infect and replicate inside host independently) interact and complement each other. This YkV1/YnV1 interaction is also distinct from those interactions between helper viruses and subviral elements (like satellite or defective viruses). Unlike satellite or defective viruses, YkV1's genome is replicated by its own RdRp.

In this article, we will be discussing genome characteristics of the two viruses and their unique mutualistic interplay in *R. necatrix*. In addition, we give an overview of other viruses or virus-like entities that may have similar YkV1/YnV1-like partnerships.

Virion Morphology

Particles formed by YnV1 are spherical in shape and approx. 40 nm in diameter (Fig. 1). The YkV1 virus genome and RdRp are also encased by the same capsid.

Genome Characteristics of YnV1

At least three different strains of YnV1 (designated as YnV1-A, B and C) have been reported so far from *R. necatrix*, while a strain from *Sclerotium rolfsii* with sequence similarity to YnV1 has been partially characterized. All three YnV1 genomes are composed of a single

Fig. 1 Electron micrograph of negatively stained virus particles. The scale bar represents 20 nm. Courtesy of Dr. Hideki Kondo at Institute of Plant Science and Resources, Okayama University.

dsRNA element. The lengths of YnV1-A (GenBank Accession No. LC061478), B (LC006254) and C (LC006256) are 8971 bp, 8958 bp, and 8952 bp, respectively. The genome of YnV1-A contains two open reading frames (ORFs), ORF1 (4965 bp) and ORF2 (3339 bp). YnV1-A harbors the 5' and 3' untranslated regions (UTRs) of lengths 150 bp and 392 bp, respectively. YnV1-A ORF1 encodes a capsid protein with the presence of a zinc finger-like motif at the N-terminal side (Fig. 2). The ORF2 encodes a putative RdRp that contains a Phytoreo_S7 (pfam07236) domain upstream of the RdRp motifs (Fig. 2). All the domains identified on YnV1-A are also conserved in YnV1-B and C.

The Phytoreo_S7 domain has been conserved across different virus families including *Reoviridae*, *Chrysoviridae* and *Endornaviridae*. It is assumed that this domain has been transferred horizontally between fungal and plant viruses over evolutionary time. In several non-phytoreoviruses, the domain is located downstream of RdRp, while like members of *Endornaviridae* and *Chrysoviridae*, the YnV1 Phytoreo_S7 domain is located upstream of the RdRp domain. Regarding the function of this domain, a previous study demonstrated that the minor inner core protein of rice dwarf virus (a phytoreovirus) with Phytoreo_S7 domain possessed dsRNA binding capability. Therefore, this domain could be associated with viral RNA synthesis occurring at the inner core of particles. The exact role of the Phytoreo_S7 domain in YnV1 is yet to be determined.

Pairwise comparison showed 8%–10% sequence divergence at the amino acid level in the CP regions among all three strains of YnV1, while the sequence divergence was only 6%–7% between their corresponding RdRp regions. It is predicted that YnV1 CP is processed either by self-cleavage activity of YnV1 itself, or by host-derived proteases.

Genome Characteristics of YkV1

The ssRNA genome of YkV1 is 6310 bp in length, presumably existing in the host as dsRNA replicative form. The genome contains a single large ORF (4293 bp), encoding a putative polyprotein with the RdRp domain, situated close to the center of N-terminal portion (Fig. 2). The lengths of its 5' and 3' UTR regions are 796 bp and 1221 bp, respectively. In addition to the RdRp domain, YkV1 also contains a picornavirus 2A-like domain (Fig. 2). This domain was first reported in the foot-and-mouth disease virus (FMDV) and later in several other members of the family *Picornaviridae* and diverse viruses like animal dsRNA toti-like viruses and reoviruses.

The picornavirus 2A is a self-processing or ribosome skipping peptide that separates structural proteins from replication-associated proteins by cleaving a growing polyprotein at the C-terminal side of a conserved motif, DxE_xNPGP (where x is any amino acid). The cleavage or ribosomal skip occurs co-translationally, which is totally distinct from that of bona fide protease-associated cleavages of viral polyproteins. The YkV1 polyprotein is also predicted to undergo self-processing or ribosome skipping mediated by the 2A-like motif.

Recently, a next-generation sequencing approach combined with Sanger sequencing identified a single Spanish *R. necatrix* isolate (Rn454) to harbor three additional yado-kari viruses designated as YkV2, YkV3 and YkV4. While YkV2 contains a single large ORF like its YkV1 counterpart, the genome of YkV4 consists of two ORFs (Fig. 2). Interestingly, YkV3 has two genome variants, one with a single-ORF organization and the other one with a double-ORF arrangement just like YkV4. Notably, another Spanish isolate, Rn95-16, of *R. necatrix* harbored YkV4. YkV2 to YkV4 share greater sequence similarity (approximately 60% identity in the RdRp region) with one another than with YkV1 (approximately 30% identity). A feature distinguishing YkV1 from YkV2 to YkV4 is the presence of a poly(A) tail at the 3' end of the genome. Notably, the 2A-like motifs of YkV1 and YkV2 are situated almost at the same position where ORF1 of YkV3 (two-ORF variant, not shown in Fig. 2) and YkV4 ends (Fig. 2). This

Fig. 2 Schematic representation of the genomic organization of yado-nushi virus 1 (YnV1) and all four yado-kari viruses (YkV1, YkV2, YkV3 and YkV4). The RdRp domains are highlighted in red for all the viruses. The zinc-finger and Phytoreo_S7 motifs on YnV1 are highlighted in purple and green, respectively. In the YnV1 genome, -1 FS indicates a possible -1 frameshift. The arrows indicate the cleavage positions within the conserved 2A-like domains (between amino acids G and P) of YkV1, YkV2 and YkV3. Molecular weight (in kDa) of each putative polypeptide has been mentioned on top of their corresponding open reading frames (ORF).

suggests the possibility that yado-kari viruses may encode at least two distinct polypeptides, *i.e.*, the RdRp for genome replication and transcription and another putative protein with unknown function.

Phylogenetic Placements of YnV1 and YkV1

The ORF1-encoded CP of YnV1 has no significant sequence similarity with any of the viral proteins deposited so far to GenBank. However, the ORF2-encoded putative RdRp showed modest levels of sequence identity to corresponding regions of dsRNA viruses such as *Giardia lamblia* virus (GLV) and *Glomus* sp. RF1 medium virus (GRF1V-M). Phylogenetically, YnV1 is also distantly related to relatively common dsRNA mycoviruses, *i.e.*, members of the families *Toti*-, *Quadri*-, *Megabirna*-, *Chrysoviriidae*, and the proposed family *Fusagraviridae* such as *Sclerotinia sclerotiorum* dsRNA mycovirus-L (also known as *Sclerotinia sclerotiorum* non-segmented virus L or SsNsV-L) (Fig. 3(A)).

Phylogenetic analysis with putative RdRp region of YkV1 showed that it is most closely related to the viruses like *Penicillium aurantiogriseum* foetidus-like virus 1 (PaFIV1), *Aspergillus foetidus* slow virus S2 (AfV-S2) and *Fusarium poae* mycovirus 2 (FpMyV2) (Fig. 3(B)). Interestingly, phylogenetically, YkV2, YkV3, and YkV4 are more closely related to FpMyV2 than to their Japanese counterpart YkV1. Indeed, based on RdRp-based phylogenetic analysis, it can be assumed that yado-kari viruses are distantly related to animal-infecting (+)ssRNA viruses belonging to the *Caliciviridae* family. It is noteworthy that both the families, *Totiviridae* and *Caliciviridae* are members of the extended picorna-like superfamily and are assumed to share the same ancestor.

Proposed Replication Model for YnV1 and YkV1

It is anticipated that, like other typical dsRNA viruses, YnV1 replicates and transcribes its genome using its own RdRp. YkV1 hijacks capsids from YnV1 and utilizes them as its replication site (Fig. 4). As the RdRp of YkV1 is also encased inside the YnV1-encoded capsid, both replication (synthesis of negative-strand RNA) and transcription (synthesis of positive-strand RNA) are presumed to be carried out by its own RdRp. This way, despite being a ssRNA virus, YkV1 likely exploits a replication strategy similar to a dsRNA

Fig. 3 Phylogenetic trees constructed with amino acid sequences of RNA-dependent RNA polymerase (RdRp) regions from (A) yado-nushi virus 1 (YnV1) and (B) yado-kari virus 1 (YkV1), and their related viruses. The figure has been reproduced with permission from Hisano, S., Zhang, R., Faruk, M.I., Kondo, H., Suzuki, N., 2018. A neo-virus-lifestyle exhibited by a (+)ssRNA virus hosted in an unrelated dsRNA virus: taxonomic and evolutionary considerations. *Virus Research* 244, 75–83.

virus inside its fungal host. This model clearly distinguishes YkV1 from other satellite RNAs or satellite RNA viruses that may or may not encode their own CP, but surely do not encode their own RdRp, therefore depending upon RdRp of their corresponding helper viruses.

Fig. 4 Proposed model for mutualistic interactions between yado-nushi virus 1 (YnV1) and yado-kari virus 1 (YkV1).

Molecular Entities Sharing Similar YkV1/YnV1-Like Interactions

The novel interplay between YkV1 and YnV1 can be misinterpreted with similar satellite and their helper/dependent virus interactions. Satellite or defective RNAs and viruses are associated with helper viruses. For genome replication, they must depend upon their corresponding helper viruses. By contrast, YkV1 encodes its own RdRp and therefore, for genome replication, it does not depend upon YnV1, although YkV1 diverts the capsid of YnV1 as its replication site.

It seems that YkV1/YnV1-like mutualistic virus-virus interactions between unrelated viruses may not be so uncommon in nature. Umbraviruses with a (+)ssRNA genome do not encode CP, therefore forming no particles. Unlike YkV1, umbraviruses are speculated to replicate in rearranged host membranes like other (+)ssRNA viruses, infecting their hosts systematically and independently of their helper viruses. For encapsidation and aphid transmission, they solely depend on (+)ssRNA assistant viruses, *i.e.*, luteoviruses, which are distinct from umbraviruses. In the absence of luteoviruses, the umbravirus genomes form filamentous ribonucleoprotein structures and their ORF3 and ORF4 products are predicted to help them in long-distance (to cause systemic infection) and cell to cell movement, respectively. Apparently, YkV1 does not have this type of survival mechanism in the absence of YnV1.

Papaya sticky disease or “meleira” is a common disease of papaya in Brazil and Mexico. The causal agent of the disease is a complex mixture of a dsRNA virus, a tentative member of the proposed family Fusagraviridae, named papaya meleira virus (PMeV) and a (+)ssRNA virus termed papaya meleira virus 2 (PMeV2). The genome of PMeV is approximately 10 kbp in size, contains two ORFs, encoding a putative CP and an RdRp. This virus can only produce typical disease symptoms when being accompanied by another 4.5 kb ssRNA virus, PMeV2. The genome of PMeV2 contains two ORFs and is closely related to umbraviruses, while no homolog of the umbravirus movement protein is detected in PMeV2. Like YkV1, the genome of PMeV2 is trans-encapsidated by the CP of PMeV. Unlike the aforementioned umbravirus-luteovirus interplay, PMeV2, a ssRNA virus, behaves like YkV1 and acquires CP from the dsRNA fusagravirus, PMeV, which acts like YnV1 in this case. PMeV2 helps PMeV to establish severe disease symptoms to papaya plants. Despite the fact that PMeV does not encode any movement proteins, it can cause systemic infection in papaya. It is assumed that the virus uses laticiferous vessels for systemic movement in the plant. It would be interesting to examine the role of the PMeV2 ORF1-encoded hypothetical protein in cell to cell or long-distance virus movement.

Another example of comparable virus-virus interplay is the interaction between rice tungro bacilliform virus (RTBV) and rice tungro spherical virus (RTSV). Rice tungro is a devastating disease of rice especially in the south and south east Asia causing significant impairment in rice production each year. The disease is caused by two morphologically different viruses: RTBV, a reverse-transcribing dsDNA virus (pararetrovirus) that forms bacilliform capsids, and RTSV, a (+)ssRNA virus that forms isometric capsids. In the case of mixed infection, both the viruses are transmitted in a semi-persistent manner by leafhoppers. However, on its own, RTBV is not transmitted by leafhoppers; for this, it depends on RTSV. While RTSV can infect plants individually, causing either asymptomatic or mild disease symptoms, severe disease manifestation occurs only when it is accompanied by RTBV.

A similar mutualistic relationship also exists between human hepatitis B virus (HBV, a dsDNA hepadnavirus) and a viroid-like circular (–)ssRNA virus satellite, hepatitis D virus (HDV, deltavirus). HDV is well-known for encoding a ribozyme and hepatitis delta antigen (HDAg). However, for the completion of its life cycle (virion assembly, transmission and cell to cell movement), HDV requires its helper virus HBV. Again, while YkV1 encodes its own RdRp for independent genome replication, HDV depends on host RNA polymerase II and its own ribozyme to replicate in a rolling-circle manner and transcribe its genome in a way similar to the

replication strategy of plant-infecting viroids belonging to the family *Avsunviroidae*. This feature is different from general satellite RNAs or satellite RNA viruses. Thus, HDV is regarded as satellite-like RNA by the International Committee of Taxonomy of Viruses.

YkV1/YnV1-Like Virus Combinations in Other Fungi

Phylogenetically, YkV1 is related to other (+)ssRNA viruses infecting different filamentous fungi than *R. necatrix* that include PaFIV1 (infecting *Penicillium aurantiogriseum*), AfV-S2 (infecting *Aspergillus foetidus*) and FpMV2 (infecting *Fusarium poae*). It is noteworthy that like YkV1, genomes of these viruses also have single-ORF architecture, encoding an RdRp with 2A-like motif at the C-terminal side of the polyprotein. Interestingly, like YkV1, PaFIV1, AfV-S2, and FpMV2 are also accompanied by either totivirus or toti-like viruses with the two-ORF genome organization. This suggests that there could be an intimate relationship between (+) ssRNA and dsRNA viruses similar to YkV1/YnV1 in other fungi as well. These combinations of viruses also share some common features. For example, the genome size of these YkV1-like (+) ssRNA viruses is always smaller than their presumed partner dsRNA virus partners. It is noteworthy that *R. necatrix* strains carrying YkV2 to YkV4 are also co-infected by multiple dsRNA viruses with the two-ORF, undivided genome architecture. However, none of these viruses, detected in the fungi harboring yado-kari viruses shared moderate levels of sequence similarity to YnV1.

Predicted Past and Future of YkV1

Phylogenetic analyses showed that YkV1 is distantly related to calici-like viruses. This suggests that it might have evolved from a calici-like virus after losing the CP. This possibility has been proposed for other capsidless ssRNA viruses as well. Most probably, after losing its CP gene, YkV1's progenitor survived inside the host by capturing CP from a co-infecting full-fledged toti-like dsRNA virus and used it as the site of replication. Another prediction is YkV1 might have evolved from a satellite RNA that somehow acquired the RdRp gene from a calici-like virus and then started hijacking CP from a co-infecting toti-like dsRNA virus. The theory of encountering a toti-like host virus is not implausible as mixed viral infection is very common in fungi, including *R. necatrix*.

In future, to become a full-fledged dsRNA virus, YkV1 needs to acquire either a CP gene from a compatible dsRNA virus (most probably a toti-like virus) or it needs to find a way to utilize host-derived membranous vesicles as its replication site, like hypoviruses.

Concluding Remarks and Future Directions

The neo-viral lifestyle of two unrelated viruses (YkV1 and YnV1) was first described in 2016. Since then, potential YkV1/YnV1-like virus combinations have been detected in other fungal hosts. It would be worth examining whether these viruses also share similar neo-viral lifestyle to the one exhibited by YkV1 and YnV1. Indeed, many aspects of this unique lifestyle are still not fully understood. Some open questions remain regarding this mutualistic interplay. (1) Does the 2A-like motif cleave the yado-kari polyprotein cotranslationally by ribosome slippage mechanism? (2) How does YnV1 efficiently trans-encapsidate the genome and RdRp of YkV1? (3) Are the YkV1 and YnV1 genomes encapsidated together or separately? (4) Where does the assembly origin of YkV1 reside in its genome? (5) What is the molecular mechanism responsible for the enhancement of YnV1 replication by YkV1? The influence of YkV1 and YnV1 on their host biology is also not fully understood. Hopefully, future research will find answers to these questions.

Ribosomal frameshifting Ribosomes changing reading

frame on an mRNA, in response to a special mRNA structure, to synthesize a protein from two overlapping reading frames.

Introduction

The L-A virus of bakers/brewers yeast *Saccharomyces cerevisiae* is the exemplar strain (ScV-L-A) of the species *Saccharomyces cerevisiae virus L-A* (genus *Totivirus*, family *Totiviridae*). L-A is one of several RNA viruses infecting this organism, each of which spreads via the cell–cell fusion of mating, rather than by the extracellular route. The totivirus L-A, like members of the very similar L-BC family of viruses (ScV-L-BC), is a single-segment 4.6 kbp double-stranded RNA (dsRNA) virus encapsidated in icosahedral particles with a single major coat protein called Gag. The 20S (*Saccharomyces* 20S RNA narnavirus, ScNV20S) and 23S RNA replicons (*Saccharomyces* 23S RNA narnavirus, ScNV23S) are naked cytoplasmic single-stranded RNA (ssRNA) replicons except for their bound RNA-dependent RNA polymerases. The L-A virus serves as the helper virus for any of several smaller satellite dsRNAs, called M dsRNAs, each encoding a secreted protein toxin and immunity to that toxin, producing the 'killer' phenomenon. Killer strains can eliminate some of the competition by this means, although less than 5% of wild strains harbor a killer dsRNA, suggesting there are costs to carrying this replicon. The killer phenotype was used to study the genetics of M dsRNAs and the helper L-A. Several functional variants of L-A were defined based on their interactions with different M dsRNAs and with the host, and host mutants affected in virus expression or propagation were also examined.

History

In 1963, Makower and Bevan reported that some yeast strains secrete a toxin that kills other yeasts. This led to the identification by Bevan and by Fink of cellular dsRNAs and later viral particles correlated with the killer phenomenon. Studies of the chromosomal genes affecting the killer system revealed that the Kex2 protease, identified by its requirement for toxin secretion, was the long-sought proinsulin-processing enzyme. The Mak3 N-acetyltransferase, whose acetylation of Gag is needed for viral assembly, established consensus sequences for such enzymes. The loss of the L-A virus in mak3 mutants revealed a second dsRNA species of the same size, called L-BC, and unrelated to the killer system.

Virion Structure

L-A virions have icosahedral symmetry, but contain 120 Gag monomers per particle, in apparent violation of the rules of quasi-equivalence. In fact, each virion is composed of 60 asymmetric dimers of Gag (Fig. 1), a feature that is common to the cores of all dsRNA viruses that have been characterized. One type of Gag molecule makes contact with the icosahedral fivefold and twofold axes, but not with the threefold axes. The second type of Gag finds itself in contact with the threefold axis, but not with either the five- or twofold axes (Fig. 1). The two environments of Gag lead to two distinct conformations, suggesting that Gag may be more flexible than some other coat proteins. The L-A virion has more volume per nucleotide than do ssRNA or dsDNA viruses. These facts may reflect the requirement that the dsRNA moves inside the particle as it is transcribed by the RNA-dependent RNA polymerase that is fixed to the inner virion wall (see below). Pores at the fivefold axes are assumed to allow entry of nucleotides and exit of (+) strand transcripts, but retention of the dsRNA genome. A trench on the outside contains His154, the central active site residue of the mRNA-decapping activity to which the 7-methyl-GMP structure becomes covalently attached (Fig. 2), and from which it can then be transferred to new viral (+) strands. A layered density observed for the viral dsRNA may reflect the dsRNA's rigid structure and the fact that it is forced to press against the inner capsid wall.

Fig. 1 Wire diagram of the L-A virus capsid. The major coat protein, Gag, is found in two nonequivalent positions: 'A' molecules contact the fivefold and twofold axes, while 'B' molecules contact the threefold axes. L-A virus at 3.4 Å resolution reveals particle architecture and mRNA decapping mechanism. *Nature Structural Biology* 9, 725–728, with permission from Nature Publishing Group.

Fig. 2 Ribbon diagram of a single Gag molecule. The trench on the outer surface includes His154, the Gag residue to which 7meGMP is covalently attached by the decapping activity.

Genome Organization

The single segment of the L-A genome is a 4.6 kbp dsRNA with two long open reading frames (ORFs) (**Fig. 3**). The 5' ORF encodes the major coat protein, called Gag in analogy with retroviruses, while the longer 3' ORF, called Pol, encodes the RNA-dependent RNA polymerase, and has homology with similar enzymes of other ssRNA and dsRNA viruses. Pol is expressed only as a fusion protein whose amino end is a nearly complete Gag molecule. The fusion is carried out by a -1 ribosomal frameshift event in the region of overlap of the two ORFs. An RNA pseudoknot, in the region of overlap of the ORFs, slows ribosome progression at a point on the mRNA (of the form X XXY YYZ (0 frame indicated)) where bonding of the A-site and P-site tRNAs to the mRNA is nearly as good in the -1 frame as in the 0 frame. About 1% of ribosomes slip into the -1 frame, and, continuing translation, make the Gag–Pol fusion protein.

Replication Cycle

Transcription

Viral particles have an RNA-dependent RNA polymerase that is due to the Pol part of the Gag–Pol fusion protein. Transcription is a conservative reaction, meaning that the parental strands remain together after the synthesis of a new (+) strand. The L-A (+) strand transcripts are extruded from the particles into the cytoplasm where they serve as both mRNA and as the species that is

Fig. 3 Genome organization. The L-A (+) strand encodes Gag and Pol in overlapping reading frames. The mRNA lacks 3' polyA structures, but gets a 5' cap stolen from cellular mRNAs. The location of the packaging site on the RNA and the region of the Pol protein segment that recognizes the packaging site are indicated. The RNA sites for replication, and the parts of Pol with homology to other RNA-dependent RNA polymerases (RdRp) are indicated. There is a cryptic in vitro RNA binding site that is inhibited by the protein region to its immediately C-terminal.

packaged by coat proteins to make new viral particles. L-A (+) strand transcripts that are not degraded immediately have two possible fates: they may be translated or they may be encapsulated. The cap-stealing activity of Gag transfers the cap 7meGMP from cellular mRNAs to some L-A (+) strands directing them to the translation apparatus, while only uncapped L-A (+) strands are encapsidated. The (+) strand transcripts of the smaller M dsRNA or of deletion mutants of L-A are often retained within the particle where they may be replicated. This is called 'headful replication' because the volume of the particle seems to be the determinant of how many dsRNA molecules may accumulate in each particle.

RNA Packaging

The RNA packaging site (Fig. 3) is a stem-loop structure about 400 nucleotides from the 3' end of the L-A (+) strand. This stem-loop has an essential A residue protruding on the 5' side of the stem. The loop sequence is also important, but the stem sequence is not critical, as long as the stem structure can form. The packaging site on the RNA is recognized by the proximal part of the Pol domain of the Gag-Pol fusion protein. The Gag part of Gag-Pol is part of the capsid structure, so the Gag-Pol fusion protein structure assures packaging of viral (+) strands in new particles.

RNA Replication

The (-) strand synthesis reaction is called replication (Fig. 4). This reaction involves recognition of the internal binding site on the L-A (+) strands by Pol, followed by interaction with the now nearby 3' end and initiation of new RNA (-) chains. Multiple rounds of RNA synthesis can proceed within the viral particle in the 'headful replication' process discussed above.

Viral Translation

The translation apparatus is the battleground of RNA viruses with their hosts. Poliovirus protease cleaves eIF4G so that host capped mRNAs cannot be translated but its own internal ribosomal entry site-containing mRNAs are used. Influenza virus steals caps from host mRNAs, as does L-A. The L-A coat protein removes caps from cellular mRNAs and transfers them to newly synthesized L-A (+) strands.

Fig. 4 Replication cycle of the L-A virus. Both (+) and (−) RNA strand synthesis occur within the viral particles, but at different stages of the cycle. RNA (+) strands (transcripts) are extruded from the particles and serve as both mRNA and the species packaged to make new particles. The (+) strands with a cap are translated while those without a cap are encapsulated or degraded. Translation of viral mRNA is blocked by Ski proteins. N-terminal acetylation of Gag by Mak3p is necessary for viral assembly.

L-A (+) strand transcripts lack the 3′ polyA structures typical of eukaryotic mRNAs, and so are at a distinct disadvantage for translation. The requirement for 3′ polyA structure for translation, is imposed by the ribosome-associated Ski (superkiller, after the phenotype of the mutants) proteins (except Ski1p/Xrn1p). These Ski proteins both degrade non-polyA mRNAs and block their translation. In the absence of these Ski proteins, non-polyA mRNAs are expressed with the same kinetics as polyA + messages. The SKI1/XRN1 gene encodes a 5′ → 3′ exoribonuclease specific for uncapped mRNA. As a defense against its degradation of viral mRNA, L-A's Gag protein has a decapping activity that removes caps from cellular mRNAs, transfers them to viral (+) strands protecting them from Ski1p, and leaves some cellular mRNAs as 'decapitated decoys', uncapped RNAs that may serve as alternative targets for the exonuclease action. In the absence of this decapping activity, viral mRNAs are not expressed, but deletion of the SKI1/XRN1 gene restores viral mRNA expression.

Together with the Ski proteins, a mitochondrial nuclease, Nuc1p, is released during meiosis/sporulation and protects cells from toxin overexpression during this process. Nuc1p is homologous to EndoG, an apoptosis nuclease of mammals, suggesting an evolutionary origin of apoptosis as an antiviral process.

L-A Genetics

Several natural variants of L-A have been described. The ability of an L-A variant to support M dsRNA replication was first called [HOK] (helper of killer) and then H when it was found to be a property of L-As such as L-A-H, L-A-HN, or L-A-HNB. Making

several chromosomal MAK genes dispensable for M propagation was named [B] (bypass) and is found on L-A-HNB. Ability to exclude L-A-H was named [EXL] (exclusion) and then just E on L-A-E. Insensitivity to the action of [EXL] was called [NEX] (nonexcludable), and then shortened to N as in L-A-HN or L-A-HNB. The molecular basis of these interactions has resisted study because of the current inability to obtain L-A dsRNA from a cDNA clone. M dsRNA can be supported from a cDNA clone of L-A, but the L-A virus has not been shown to be regenerated from these transcripts.

Other RNA Replicons in Yeast: L-BC, 20S RNA, 23S RNA

20S RNA was discovered as an RNA species which appeared when cells were placed under conditions that induce meiosis and spore formation, namely near-starvation for nitrogen and provision of acetate as a carbon source. It was shown that 20S RNA is an independent replicon, and can be made independent of the sporulation or meiosis processes. 20S RNA encodes its own RNA-dependent RNA polymerase which is bound to the otherwise naked cytoplasmic RNA. The mechanism of 20S RNA replication control by culture conditions remains to be elucidated. 23S RNA is a related, but independent yeast replicon which was found as a dsRNA form (called T). 23S RNA also encodes its RNA-dependent RNA polymerase. Both 20S RNA and 23S RNA can be launched from cDNA clones to form replicating virus. 20S RNA (ScNV20S) and 23S RNA (ScNV23S) are classified into the genus *Narnavirus* within the family *Narnaviridae*. L-BC is a totivirus (genus *Totivirus*, family *Totiviridae*), related to L-A but independent of it. Its dsRNA is essentially the same size as that of L-A although its copy number is usually about tenfold lower. Thus it was not detected until chromosomal mutants that lose L-A were examined. L-BC does not interact with the killer system, and confers no obvious phenotype, so its genetics has not been extensively explored.

RNA Viruses Infecting Marine Protists

Most studies on marine RNA viruses have been on those infecting either charismatic megafauna or animals of economic importance. Over the last three decades this research has extended to include RNA virus isolates infecting protists as well as RNA metagenomic studies. Through this, the known marine RNA viruses now include representatives of all four Baltimore RNA virus groups, with hosts spread across the eukaryotic tree of life. Of these viruses, those infecting single-celled eukaryotes are thought to be the dominant portion of the free-floating RNA virus community.

The first RNA virus isolated and characterized that infects a marine protist was Heterosigma akashiwo RNA virus (HaRNAV). This virus was isolated from the Strait of Georgia in coastal British Columbia and it infects and causes the lysis of the marine, toxic bloom-forming, unicellular, photosynthetic alga *H. akashiwo*. HaRNAV particles are non-enveloped icosahedrons, with an average diameter of 25 nm (Table 1). The positive-sense monocistronic genome is 8.6 kb in size and has distinct domain organization characteristics that contributed to its classification as the founding member of the family *Marnaviridae* within the order *Picornavirales*. The polyprotein translation is under the control of a putative 5' internal ribosome entry site (IRES), with the non-structural proteins (helicase [S3H], 3C protease [3CPro], and RNA-dependent RNA polymerase [RdRp]) encoded at the N terminus and the structural proteins (VP2, -4, -3, and -1) at the C terminus (Fig. 1). HaRNAV particles become visible within infected cells 48 h post infection. Like other RNA viruses it has a relatively large burst size, at 460–520 particles per cell. One notable sign of viral-induced intracellular cytopathology is the appearance of membranous vesicles within the cytoplasm; such structures are the site of RNA replication for other positive-sense single-stranded (ss) RNA viruses and are well characterized for picornaviruses such as poliovirus. This is followed by the appearance of assembled viral particles throughout the cytoplasm, and these can be at sufficient density for the particles to form crystalline arrays.

Additional icosahedral (25–32 nm in diameter) ssRNA viruses (genomes ranging from 4.4 to 13.2 kb) infecting other marine protists have since been isolated and characterized. These include the dinoflagellate-infecting *Heterocapsa circularisquama* RNA virus (HcRNAV) of the family *Alverniviridae*, *Chaetoceros tenuissimus* RNA virus types I and II (CtenRNAV01 and CtenRNAVII), *Chaetoceros socialis* f. *radians* RNA virus (CsfrRNAV), *Chaetoceros* sp. (CspRNAV) and *Rhizosolenia setigera* (RsRNAV) RNA viruses that infect centric diatoms, the pennate diatom-infecting *Asterionellopsis glacialis* RNA virus (AglRNAV), and *Aurantiochytrium* RNA virus (AuRNAV), which infects a heterotrophic marine flagellate. There is also one known double-stranded (ds) RNA virus infecting a marine protist, MpRNAV-01B, which infects the photosynthetic *Micromonas pusilla* and represents the only species in the genus *Mimoreovirus*, subfamily *Sedoreovirinae*, family *Reoviridae*. Some studies have suggested other protist RNA viruses might exist in cultures. Two notable examples are the observation of RNA virus-like particles in *Ostreococcus* sp. and the determination of RdRp sequences for two viruses that infect the pennate diatom *Cylindrotheca closterium*. Recently, the potential host range of protist-infecting RNA viruses has also been extended to the holobiont of the multicellular protist *Delisea pulchra*. The detected viruses included + ssRNA viruses affiliated to the *Picornavirales* as well as some dsRNA viruses with sequence similarity to members of the *Totiviridae*. Metagenomic studies focused on planktonic marine RNA viruses have also revealed many novel viruses, including some complete viral genomic sequences. The majority of these show affiliation with the order *Picornavirales*.

Development of a Taxonomic Framework and Resulting Changes in Taxonomy

In addition to HaRNAV's classification as the founding member of the family *Marnaviridae*, four of the above-mentioned + ssRNA viruses had previously been formally taxonomically classified. These are AuRNAV, classified within the unassigned genus *Labymavirus*, and CtenRNAV01, CsfrRNAV and RsRNAV, which were classified within the unassigned genus *Bacillamavirus*. Until recently, the International Committee on the Taxonomy of Viruses (ICTV) taxonomic classification system required inclusion of biological information such as host range, replication cycle, virus particle structure, and serology. However, recognizing the need to update the taxonomic system, the ICTV recently announced they would accept the formal taxonomic classification of viruses known only from metagenomic studies. We have recently applied a sequence-based framework for analysis of twenty marine RNA viruses that provides the justification for taxonomic classification of these viruses within the family *Marnaviridae*. The 20 viruses include the original and sole representative of the family, HaRNAV, 7 additional viruses represented by isolates, and 12 viruses discovered using metagenomics. Phylogenetic analysis of the RdRp domain sequences placed the 20 marine RNA virus sequences in a strongly supported monophyletic group relative to other *Picornavirales* sequences (Fig. 2). The original genus within the *Marnaviridae*, *Marnavirus*, is basal within the clade and the analysis places the 20 viruses into seven clades that we defined as genera within the family *Marnaviridae*. These include the

Table 1 Isolates in the family *Marnaviridae* that infect marine protists

<i>Virus</i>		<i>Host</i>		<i>Genus</i>	<i>Particle diameter (nm)</i>	<i>Genome size (kb)</i>	<i>Latent period (hours)</i>	<i>Burst size (particles per cell)</i>

^aND, not determined.

Fig. 1 Viral genomic organizations of members within the family *Marnaviridae*. The isolates and metagenomic-assembled viruses have either a mono- or dicistronic genome organization, which include a putative 5' internal ribosome entry site (IRES), S3 helicase, 3C protease/peptidase, RNA-dependent RNA polymerase (RdRp), putative intergenic region (IGR) IRES (in dicistronic genomes), four capsid domains (VP2, VP4, VP3, and VP1), and a poly(A) tail.

Fig. 2 Unrooted maximum-likelihood phylogeny of the RNA-dependent RNA polymerase amino acid sequences of members in the order *Picornvirales*. Sides of grey triangles represent longest and shortest branches with the base width indicating of the number of genera present in the collapsed clade. Members of the family *Marnaviridae* are coloured by genus: *Marnavirus* (blue), *Labynavirus* (red), *Locarnavirus* (purple), *Kusarnavirus* (yellow), *Bacillarnavirus* (pink), *Salisharnavirus* (orange), and *Sogarnavirus* (green). SH-like branch support values are indicated at nodes when >0.70 and the scale bar indicates substitutions per site.

Table 2 Species in the family Marnaviridae

Genus	Species	Virus name	Abbreviation	Accession number	Size (nt)	Source
Marnavirus	<i>Heterosigma akashiwo</i> RNA virus ^a	<i>Heterosigma akashiwo</i> RNA virus	HaRNAV	NC_005281	8587	<i>Heterosigma akashiwo</i>

^aType species.

previously unassigned genera *Bacillarnavirus* and *Labyrnavirus*, and we chose the names *Kusarnavirus*, *Locarnavirus*, *Salisharnavirus* and *Sogarnavirus* for the four new genera. Capsid polyprotein sequence comparisons were used to delineate the species within genera (Table 2), with a cut-off of 75% pairwise amino acid identity.

Among the 20 viruses and 7 genera, there is a mixture of mono- and dicistronic genome organizations (Table 1; Fig. 1). While the majority of the 20 viruses have a dicistronic genome organization, HaRNAV and SF-3 have a single predicted polyprotein encoded in their genomes. HaRNAV is the only representative of the genus *Marnavirus*, but SF-3 is one of four viruses falling within the genus *Locarnavirus*. There is precedent for such different genomic organizations within the *Picornavirales*, with both mono- and bipartite genomes found within the *Secoviridae*.

Marine RNA Virus Quasispecies

RNA viruses exist in a mutation-selection balance where a genetically diverse population of variant genomes are ordered around the fittest genome from a single progenitor, known as the quasispecies concept, and this is important in the evolution of RNA viruses. Single-nucleotide variance analysis of six of the *Marnaviridae* members' sequences identified in RNA virus metagenomic data sets from around the globe suggest that these viruses also exist as quasispecies, with many low frequency mutations detectable across conserved domains. The distribution of viral genotypes across marine waterbodies is poorly understood. Patterns in the variant analysis showed that some of the viruses exhibited quasispecies-like populations with synonymous low-frequency mutations in locations distinct from the original site of discovery. Some mutations provide a competitive advantage to the virus, and they can become established in the viral population. Mutations occurring at >99% frequency were detected in these datasets across multiple viral domains and geographic locations, which indicates turnover of the dominant genotypes had occurred.

Importance of RNA Viruses in Marine Microbial Ecology

It has traditionally been believed that most of the estimated 10^7 marine virus particles per ml of seawater have DNA genomes and infect bacteria. Viral abundance is most frequently determined using epifluorescence or electron microscopy, or flow cytometry. These methods are good for detecting larger DNA viruses, but they lack the sensitivity and specificity to detect small RNA genomes

or, in the case of electron microscopy, differentiate RNA viruses from small DNA viruses. Use of fluorometry to determine the abundance of RNA- and DNA-containing virus particles suggested that at least 50% of the viroplankton in coastal waters have RNA genomes. Using quantitative RT-PCR, picorna-like RNA virus genome abundances were estimated to range from 0.2 to 5×10^7 per ml, thereby representing 14%–90% (mean approximately 40%) of the total coastal marine virus populations sampled. If this holds true for other marine environments, it could have huge implications for our understanding of viral production and the contribution of RNA viruses to biogeochemical processes. Considering that the majority of viruses identified in the study were picorna-like viruses, known to infect eukaryotes, we can assume that protists actually contribute more to marine viral dynamics than previously thought.

The hosts for the isolated *Marnaviridae* members (Table 1) include ecologically important protists and these viruses are thought to have significant effects on both the frequency and duration of plankton blooms. For example, HaRNAV infects the bloom-forming Raphidophyte *Heterosigma akashiwo*. Only some strains of *H. akashiwo* are susceptible to infection by HaRNAV, and the pattern of susceptibility does not appear to relate to geographic origin of the strain in question. When the virus is added to a growing culture of susceptible *H. akashiwo*, complete lysis of the culture generally occurs within 1 week or less. Diatoms are integral members of marine phytoplankton communities and represent the largest proportion of host organisms for viruses in the family *Marnaviridae*. Diatoms are distributed worldwide and are responsible for 35%–75% of the primary production in the oceans. Diatom blooms occur seasonally in nutrient-rich ecosystems, where a succession of species is observed. Like HaRNAV, the studied diatom viruses are highly host specific, frequently exhibiting strain specificity. Although burst sizes range widely, from 66 (CsfrRNAV) to 1.0×10^5 (CtenRNAV01) particles per cell, these viruses can decimate host populations and alter population dynamics, species succession and the functioning of the biological carbon pump.

The survival of host cells within a pool of viral pathogens suggests that there are regulatory factors affecting successful infection. For example, *C. tenuissimus* was found to be consistently detected at high abundances in both seawater and sediments off the coast of Japan where viruses infecting it are also known to occur in high abundance. While virus resistance could account for some of this, environmental niche partitioning was also shown to be an important contributor to viral infection, with temperature and salinity affecting viral infections of the same host organism.

Summary

Work in the ocean, with both culturing and metagenomics approaches, has shown that marine systems harbor a whole new world of ssRNA viruses. The majority of these have shown affiliation with the order *Picornavirales*, and many of these have now recently been formally classified within the family *Marnaviridae*. However, despite their shared characteristics and phylogenetic affiliations based on conserved domains, most of the genomes have no recognizable similarity to any other known sequences, viral or otherwise. More work is clearly needed with the individual marine RNA viruses, and even more viruses need to be brought into culture, sequenced and characterized. The ssRNA viruses isolated from marine systems infect basal eukaryotes, protists, and so these viruses may be ancestral to the related viruses infecting higher organisms such as mammals. There is no doubt that study of marine RNA viruses will further our understanding of RNA virus evolution.

Glossary

Algal viruses Viruses infecting eukaryotic algae.

Intein An intein is a “protein intron” that catalyzes self-splicing at the protein level. The self-splicing is carried out by the autocatalytic excision of the intein from a precursor host protein where it is located, and the concomitant ligation of the flanking protein segments (“exteins”) of the precursor. Inteins often possess a homing endonuclease domain, which confers the mobility on the intein-encoding DNA.

MIGE (Major Interspersed Genomic Element) Repeated sequences throughout genomes.

NCLDV Nucleocytoplasmic large DNA viruses is a proposed order of viruses containing several families that all share certain genomic and structural characteristics.

NCVOG Nucleo-Cytoplasmic Virus Orthologous Groups is a database for homologous genes vertically inherited within at least one viral family in the NCLDV group.

ORF Open reading frame, the part of a reading frame that has the ability to be translated.

Phylogenetic diversity A measurement of biodiversity which incorporates phylogenetic difference between species.

Phylogenetics The study of evolutionary history and relationship among individuals or groups of species or populations.

Taxonomic richness The number of different taxa represented in an ecological community.

Virophage Small double stranded DNA viruses that require the co-infection of another virus for the replication.

History

During the last decades it has become clear that viruses are the most abundant biological entities in aquatic environments. By their lytic activity, viruses are linked to several vital ecological processes, such as the structuring of host communities, and biochemical cycling. They are also key players in the evolution of their hosts. Viral abundances in aquatic systems are typically in the order of 10^6 – 10^7 viruses per mL, and it is estimated that viral lysis is responsible for releasing as much as 10 billion tons of organic carbon into the ocean per day. Viral activity contributes not only to nutrient recycling (that fuels the productivity in the upper euphotic ocean) but also impacts the transfer efficiency of organic matter to higher trophic levels and the transport of organic matter to the depths of the oceans. The viral shunt is also proposed to increase the efficiency of the carbon pump. This is because the viral lysis of host cells releases labile NP-rich organic matter (e.g., peptides) that can be re-used to grow new cells, while the less labile, carbon enriched (e.g. cell wall), part of the host cell tend to aggregate and sink.

Most of the marine viruses infect the numerically dominant microorganisms, including the unicellular algae (phytoplankton). As early as 1981 large icosahedral viruses infecting *Chlorella* were reported and in 1982 a virus infecting the photosynthetic protist *Micromonas pusilla* was described. Currently viruses have been isolated for all taxonomic groups of phytoplankton. Originally, all double-stranded (ds) DNA icosahedral viruses infecting photosynthetic protists were first classified into the family *Phycodnaviridae*. Recent phylogeny based on Nucleocytoplasmic Large DNA Viruses (NCLDV) orthologous genes, however, shows that many of the large dsDNA algal viruses belong to the family *Mimiviridae* (Fig. 1). The enormous diversity found within this family suggests that *Mimiviridae* has a deep co-evolutionary history with its marine protists hosts, dating back to the early history of life. The families *Mimiviridae* and *Phycodnaviridae* have been shown to dominate the NCLDV populations in marine metagenomes with concentrations up to $>10^4$ genomes per mL in the photic zone. In this article we describe the phytoplankton viruses belonging to the *Mimiviridae* family.

One of the first isolated large dsDNA viruses, that was later assigned to the *Mimiviridae* family, was *Phaeocystis pouchetii* virus (PpV) isolated in 1995. A few years later (1998) two more viruses, belonging to this subgroup, were characterized, namely *Chrysochromulina ericina* virus (CeV 01B) and *Pyramimonas orientalis* virus (PoV 01B). The genome size of these viruses were the largest ever reported at that time with sizes being 474 and approx. 560 kbp, respectively. All these viruses were isolated from coastal waters in a Norwegian fjord (Raunefjorden). Some years later (2005), characterization of different *Phaeocystis globosa* viruses (PgVs), isolated from the southern North Sea, was published. Some of these PgV viruses belong to the family *Phycodnaviridae* and are denoted PgV Group II, whilst those belonging to the family *Mimiviridae* are called PgV Group I. PgV-16T (Group I, genome size: 460 kbp) was the first of the algal mimiviruses (members of the family *Mimiviridae*) to be fully sequenced (in 2013). In the following decade several new viruses have been linked to this family, namely *Aureococcus anophagefferens* virus (AaV), *Haptolina ericina* virus (HeV RF02), two *Prymnesium kappa* viruses (Pkv RF01, Pkv RF02), *Prymnesium parvum* virus (PpDNAV), and *Tetraselmis* virus (TetV-1). In addition, metagenome assembled genomes have been recovered for three non-isolated *Mimiviridae*, i.e., two organic lake phycodnaviruses (OLPV 1 and 2) and Yellowstone lake mimivirus (YSLGV). The

Fig. 1 Maximum likelihood phylogenetic reconstruction on DNA polymerase family B (PolB) using RAXML. Members of *Phycodnaviridae* were used as an outgroup. Circles between internal nodes indicate bootstrap values above 70% (light gray), and above 90% (dark gray). Viral host are color coded by heterotrophs (blue) and phototrophic algae (green). The scale bar indicates the average number of substitutions per site. The proposed subfamilies *Megavirinae* and *Mesomimivirinae* are not yet approved by the ICTV.

two firsts are nearly-complete genomes while the third one is partial. These three viruses are phylogenetically most related to algae-infecting mimiviruses suggesting that phytoplankton are their hosts. As early as 2005 the search of mimivirus proteomes against Sargasso Sea metagenomes, both concomitantly released a year before, indicated the presence of mimivirus-relatives in marine environment. Following analyses of several marker gene sequences (DNA polymerase type B, DNA-directed RNA polymerase (RNAPol)), asparagine synthetase (AsnS) and DNA mismatch repair enzyme (MutS) from various marine genomic datasets hinted to the vast phylogenetic diversity of *Mimiviridae* and their large taxonomic richness. Recently, diversity analysis of DNA-directed RNA polymerase subunits 1 and 2 fetched from bacteria-sized metagenomes collected during the *Tara* Oceans expedition indicated that the taxonomic richness of the family *Mimiviridae* exceeds that of a domain of cellular organisms (i.e., Bacteria). Importantly, the vast majority of this untapped diversity falls in the vicinity of the algae-infecting rather than heterotroph-infecting clade, although their host may include non-photosynthetic organisms.

General Properties

All so far isolated algae-infecting viruses in the *Mimiviridae* family have icosahedral structures between 130 up to 310 nm in diameter and dsDNA genomes. They all replicate in the cytoplasmic area (defined as virus factories) of the host cells, thanks to their own well-conserved transcription machinery, and produce lytic viruses that are transmitted horizontally. The latent time ranges from 10 to 72 h (Table 1). Phylogenetic analysis of DNA polB (Fig. 1) shows that they group in a strongly supported monophyletic group within the *Mimiviridae* family, most similar to viruses infecting heterotrophic protists and less to viruses infecting other autotrophic protists in the *Phycodnaviridae* family. Nevertheless, several genes of *Phycodnaviridae* origin are detected in the genomes of *Mimiviridae* viruses, suggesting a common origin. A comparative genomics study between NCLDV reported

22 proteins unique (not seen in other NCLDV) to the *Phycodnaviridae-Mimiviridae* clade and a conservative estimates of 74 proteins present in their last common ancestor. As a comparison these numbers were respectively 27 and 66 for the Chordo/Entomo-poxvirus clade, whose shared ancestry is well acknowledged. It should be noted that the genomes of algae-infecting mimiviruses as well as the distant phycodnavirus *Heterosigma akashiwo* virus HaV53 were not available at that time for comparison. Among the 22 previously reported proteins unique to the *Phycodnaviridae-Mimiviridae* clade, those with notable functions and also encoded in some algae-infecting mimiviruses are transcription factor TFIIB, putative glycosyltransferases, prolyl hydroxylase, DNA J like chaperone and cytidine/deoxycytine deaminase.

Four of the isolated viruses are fully sequenced with genome sizes ranging from 340 to 668 kbp (Table 1). Three of the viruses have linear genomes (CeV, PgV-16T, and AaV), while the genome of TetV-1 is circular. Most of these genomes exhibit high A + T contents, with G + C contents between 23%–32%. One exception is TetV, that has a G + C content of 41% (Table 1). A general feature for these viruses is a relatively low share of common “core” genes and a high proportion of unique genes that is not shared with other members within the *Mimiviridae* family. Of the NCLDV orthologous genes, DNA polB (NCVOG0038), Major capsid protein 1 (MCP1, NCVOG0022), A32-like virion packing ATPase (NCVOG0249), RNAPol (RNA pol subunit I: NCVOG0274 and subunit II: NCVOG0271), asparagin synthase (AsnS, NCVOG0061), eukaryotic translation initiation factor 4E (eIF-4E, NCVOG4661) and MutS7 (NCVOG2626) are all shared in the sequenced mimivirus genomes (Table 2), except AaV that is missing AsnS and eIF-4E homologs. DNA repair enzymes are essential for cellular life but have been detected in some viruses with large genomes. Viral homologs of MutS7 shows homology to MutS7 in *Epsilonproteobacteria* and in the mitochondrial genome of octocorals. The presence of MutS7 homologs in viral genomes therefore provide strong evidence for the placement in the *Mimiviridae* family. Among these core genes, the presence of an additional copy of the RNA pol subunit 2 in the genomes of algae-infecting mimiviruses, with the exception of AaV, is a notable feature that can be used to discriminate between algae- and heterotroph-infecting members of the family *Mimiviridae*. The seven core genes mentioned above are present in the unpublished/partially sequenced genomes of PkV RF01, PkV RF02, and HeV RF02 (Table 2). For PpV, PoV, and PpDNAV, presence of only some of these genes have been tested by PCR followed by sequencing. All three viruses have DNAPolB and MCP1, while PoV and PpV contain MutS7 in addition (Table 2). None of the viruses have been tested for presence of A32-like virion packing ATPase or RNA polymerase subunit II.

Another shared feature between algae and heterotroph-infecting *Mimiviridae* viruses is the presence of several tRNAs and other proteins involved in translation. In line with their smaller genome size (Fig. 1), algae-infecting *Mimiviridae* possess less genes coding for translation related proteins compared to heterotroph-infecting mimiviruses. While mimiviruses infecting heterotrophs encode several aminoacyl-tRNA synthetases, up to 20 for *Tupanvirus soda lake* (genome size: 1.4 Mb), 7 for *Megavirus chiliensis* (genome size: 1.2 Mb) to as few as one (Ile-aaRS) for *CroV* (genome size: 730 kbp), none have been reported in TetV1, CeV 01B, PgV-16T, nor AaV. The notable exception is a catalytic domain for Asn/Asp-tRNA synthetase encoded in the genome of CeV 01B. The closest homologs to this ORF are found in *Prochlorococcus* phages P-SSM2, 5, and 7. However, algae-infecting mimiviruses possess no less tRNA genes (AaV and PgV: 8, CeV: 12, TetV:10) compared to other mimiviruses. tRNA genes tend to occur in clusters in both algae and heterotroph-infecting mimiviruses. CeV, PgV and TetV encode the translation initiation factor 4F (eIF-4E) shared and monophyletic with other mimivirus eIF-4E proteins. The stramenopile-infecting mimivirus AaV encodes the translation elongation factor eEF-1 alpha. eEF-1 alpha is shared with heterotroph-infecting mimiviruses, but not with other algae-infecting mimiviruses. AaV eEF-1 alpha has its closest homologs in genomes of diatoms (62% amino acid (aa) identity) and is very distantly related to the eEF-1 alpha of heterotroph-infecting mimiviruses (aa identity <30%). AaV additionally codes for the translation initiation factor eIF-5A, which presents 56% aa identity to a *Aureococcus anophagefferens* homolog, and the only, yet distant, viral homolog is seen in *Orpheovirus*. TetV-1 encodes the only viral homolog for the eukaryotic translation initiation factor eIF-1A. PgV-16T possesses the translation elongation factor eEF3, not seen in other *Mimiviridae*, and harboring 63% aa identity with *Emiliania huxleyi*'s eEF3. Interestingly, chloroviruses (genus *Chlorovirus*, family *Phycodnaviridae*) also encode an eEF3 sequence most similar (60% aa identity) to a homolog in *Chlorella variabilis*. The sparsity of translation factors in algae-infecting mimiviruses, and the similarity with homologs in host (or relatives), indicate recurrent acquisition of these genes from their host.

The biological underpinnings for the acquisition of these translation factors is unclear. But, it may be needed to counteract the shutdown of host translation machinery upon infection.

Seven of the ten cultured algal mimiviruses infect haptophytes belonging to the class Prymnesiophyceae, two infect hosts belonging to the Prasinophyceae and one infects a host belonging to the Pelagophyceae. These hosts are deeply separated in the eukaryotic tree demonstrating the wide span in host range for viruses belonging to this group. Most viruses infecting eukaryotic hosts are thought to be specialists, infecting only one species or strain within a species. Most (7) of the cultured algal mimiviruses are species- or strain-specific, while the other three can infect different species (HeV RF02, PkV RF01, PoV 01B). HeV RF02 and PkV RF01 both infect different strains of *Haptolina ericina* and one strain of *Prymnesium kappa*, while PoV 01B infects both one strain belonging to the *Pyramimonas orientalis* and *Haptolina ericina*, respectively (Table 1). The host groups of these algal mimiviruses are ubiquitous and diverse, found in the epipelagic layer of tropical, temperate and Arctic oceans. They play ecologically important roles in the epipelagic ocean, moreover some are forming blooms or are mixotrophs, grazing on bacteria and protists. Viral control of these host population dynamics can thus have imperative consequences for carbon and nutrient fluxes and trophic transfer efficiency.

Currently, there is no official taxonomic subdivision within the *Mimiviridae* specific for the algal viruses. In recognition of the phylogenetic affinity of the distinct clade of algae-infecting mimiviruses, and to acknowledge the clear separation of these viruses from the *Phycodnaviridae* family, the subfamily *Mesomimivirinae* was recently proposed. It encompasses CeV01B, HeV RF02, PgV-16T, PkV RF02, PpDNAV, and PpV01, together with OLPV 1 and 2 (Fig. 1). However, not all algal *Mimiviridae* viruses cluster within the *Mesomimivirinae* subfamily. Some separate into distinct lineages (Fig. 1). These are the viruses PkV RF01, AaV, and PoV 01B together with TetV-1. This group of unclassified algae-infecting mimiviruses indicates a huge diversity to be discovered and novel distinct taxonomic groups will certainly be described as more related viruses are isolated and sequenced.

Proposed Subfamily *Mesomimivirinae*

This subfamily consists of six virus isolates, all infecting haptophytes belonging to the Prymnesiophyceae. Virus characteristics vary strongly within this subfamily, as reflected in capsid size (130–221 nm) and gene contents of those two representatives that have been sequenced, namely PgV-16T (GenBank accession no. KC662249) and CeV 01B (GenBank accession no. KT820662). Both PgV-16T and CeV 01B contain genomic repeats, MIGE (Major Interspersed Genome Element), with twelve copies in the PgV genome and six copies in CeV. The MIGEs of PgV and CeV are grouped in separate clusters based on their phylogeny, indicating a separate evolution from a single copy to multicopy duplication. Another common feature between these two viral genomes is the detection of inteins. PgV-16T contains only a single intein, within the coding region of a helicase, while the genome of CeV 01B contains an unusually large number (8) of inteins that are inserted in seven different genes, strongly biased against DNA processing enzymes. Two similar inteins are detected in two unrelated genes, a Lon protease and a DEAD-box helicase. This is quite unusual as an intein normally spreads over homologous (but intein-free) genes with the use of the intein encoded homing endonuclease.

PgV-16T also contains two transposases with strong similarity with viral homologs in OLPV1 (also in two copies). Furthermore, PgV-16T also contained several DNA methylases and type II restriction endonucleases, suggesting that the viral genome contains modified nucleotides as also found for *Paramecium bursaria* Chlorella Virus 1 (*Phycodnaviridae*). An interesting feature is the finding of a virophage genome (PgVV) in the PgV-16T genome data with only three genes homologous to virophages detected in the OLPVs metagenomes and Mavirus infecting the CroV. Surprisingly, no small virions are detected in the cytoplasm together with PgV during infections. Nor is a capsid like gene detected in the PgVV genome. It is therefore suggested that PgVV exists either as a linear plasmid-like molecule, or as a randomly integrated provirus. If so, PgVV might be the first example of a virophage/transposonvirovion intermediate mobile element.

The partially assembled genome sequences of two other PgV strains (PgV-12T and PgV-14T, GenBank accession no. HQ634147.1 and HQ634144.1, respectively) showed a similarity in their gene content and identity (as high as 98% to the fully sequenced PgV-16T genome). All these PgVs are part of the Group I PgV, with similar large dsDNA genomes and clustering based on phylogeny (DNA pol B) and phenological characteristics. PgV-07T, also part of Group I, have shown to contain a lipid membrane, detected by staining with lipophilic dye and chloroform and diethyl ether treatment. Intact polar lipids (IPL) analysis displayed that the IPL composition of PgV-07T was different than its host *P. globosa* G(A). In contrast to EhV infecting the prymnesiophyte *Emiliania huxleyi*, no viral glycosphingolipids (vGSLs) were detected. PgV seems to obtain its lipid membrane in the host cytoplasm and not from the cell membrane as observed for EhV. The lipid membrane of PgV is argued to be an intracapsid membrane, similar to what is proposed for PpV (infecting *P. pouchetii*) using electron cryomicroscopy.

PgV-07T is highly sensitive to a combination of phosphate (P) limited and light stressed growth of its host, resulting in a 95% loss in infectivity of the progeny viruses. Host metabolism strongly regulates the proliferation of PgV, with prolonged latent period and reduced burst size under low and high light intensity (host energy limitation and inhibition) as well as nutrient limitation. Not only phosphorus was shown to strongly limit PgV production but also iron and in particular nitrogen limited host growth resulted in lowered burst sizes as compared to resource replete conditions (i.e., 70%, 72% and 92% reduction, respectively). *P. globosa* occurs in temperate coastal waters with strong gradients in light and nutrient availability. Overall, all hosts of the *Mesomimivirinae* viruses are found in waters with strong seasonal variability in growth-related environmental variables. With their important ecological function, the magnitude of viral control of these host species will vary temporarily, geographically and with depth.

Unclassified Algae-Infecting Members in the Family *Mimiviridae*

AaV (GenBank accession no. KJ645900) infects *Aureococcus anophagefferens* that causes “brown tides” in coastal and estuarine waters of the United States, China and South Africa. The ecological and economical consequences of these blooms is enormous as blooms inhibit penetration of light and kill seagrass and juvenile shellfish. The virus was isolated from the east coast of the United States outside New York. AaV is the smallest member of viruses infecting photosynthetic protists within the *Mimiviridae* family with a sequenced genome of 370 kbp and a capsid size of 140 nm. The genome architecture of AaV demonstrates that the ancestral virus had even a smaller genome, which has been expanded through gene duplication and assimilation of genes from several sources including its host.

AaV has been shown to be an outlier within the *Mimiviridae* family. In sequence-based analyses, AaV encodes many genes that are more similar to genes of mimiviruses than of other NCLDV and its core NCLDV genes showed higher sequence similarity, and in a number of cases, clear orthologous relationship with mimivirus homologs. However, AaV is missing the asparagine synthase, the polyA polymerase and eIF-4E present in other mimiviruses. An additional unique feature of AaV compared to other mimiviruses is a duplication of RNA polymerase II largest subunit (rpb1). Although it possesses a second, yet incomplete (222 aa against >1000 aa for canonical proteins) version of the RNA polymerase second largest subunit (rpb2), these two seem to be only distantly related as it is for other algal mimiviruses. It is also notable that twenty-two AaV genes had highest sequence similarity with phycodnavirus genes. In addition several photolyase genes and genes involved in DNA repair are found, as also found in several large DNA viruses. Phylogenetically it makes a long branch within the group unclassified algae-infecting mimiviruses, with the closest (but still distant) relative being PkV RF01 (Fig. 1).

PkV RF01, infecting the haptophytes *P. kappa* and *H. ericina*, has the largest capsid size (310) of all the so far cultured algae-infecting mimiviruses. Interestingly, PkV RF01 infects the same hosts as HeV RF02 and PkV RF02 that belong to the subfamily *Mesomimivirinae* indicating the complexity of virus-host interactions and further the difficulties in naming viruses. Similar to HeV RF02, PkV RF01 is able to proliferate in more than one genus indicating that broad host range may perhaps be common in marine ecosystems as the ecological advantage seems obvious. The persistent hosts of PkV RF01, *H. ericina* and *P. kappa*, do normally not form massive blooms, as many of the hosts of other isolated algal viruses (e.g., PgVs, AaV, EhV), but are present at low densities at different seasons. As evolution between host and its parasite always will aim towards host survival rather than high mortality, these viral-host systems may represent the most typical systems in the marine environments; low-density hosts (non-blooming) and viruses that appear to have co-evolved for a long time. Although its closest yet very distant relative is AaV, PkV RF01 encodes the AsnS and eIF4-4E mimivirus core genes (Table 2).

Two mimiviruses infecting Chlorophyta have been described, namely PoV 01B and TetV-1. Both viruses have large capsid size (220–257 nm) and genomes (560–668 kbp). Based on DNA polB and MutS7 phylogeny they are more closely related to each other than to other viruses within this algal *Mimiviridae* group. PoV 01B was isolated from the western coast of Norway while TetV-1 was isolated from the coast of Hawaii. PoV 01B has unfortunately been lost from our culture collection. The genome of TetV-1 (Genbank accession no. KY322437) contains several key genes never detected in viruses before. These genes include a mannitol metabolism enzyme, a saccharide degradation enzyme and the key fermentation genes pyruvate formate-lyase and pyruvate-lyase activating enzyme. The presence of the two latter enzymes suggest that TetV-1 has the potential to manipulate its host fermentative pathway. It is speculated that green algae use fermentation to survive periods with low oxygen concentration. Thus, TetV-1 might use the viral homolog of these genes to ensure energy requirement for virus production especially after increased bacterial respiration that follows bloom termination by viruses. The saccharide degradation enzyme in TetV-1, alpha-galactosidase, is suggested to enhance cell lysis as the cell wall of *Tetraselmis* contain up to 7% galactose and 21% galacturonic acid. The same function has been suggested for the mannitol 1-phosphate dehydrogenase gene as the host, *Tetraselmis*, uses mannitol as a osmolyte under hypersaline conditions. Manipulation of such system might therefore induce host lysis.

Introduction

With the realization during the last three decades that viruses are highly abundant in various aquatic environments, interest in aquatic viruses significantly increased. Viruses are now recognized as important biological agents not only regulating population dynamics, and succession and diversity of the host organisms in marine systems, but also influencing the functioning of aquatic food webs and biogeochemical cycles (energy and matter fluxes). Members within the microbial food web can become infected by viruses, including eukaryotic algae. In the present article, we summarize the characteristics of some RNA and DNA algal viruses that do not belong to the virus families thus far established officially, e.g., *Phycodnaviridae*, *Mimiviridae*, and *Marnaviridae* (separately discussed in other chapters).

Algal single-stranded RNA Viruses

Genus *Dinornavirus*

Heterocapsa circularisquama RNA virus (HcRNAV) is a positive-sense ssRNA virus infecting the bivalve-killing, bloom-forming dinoflagellate, *H. circularisquama*, which is a type species of the genus *Dinornavirus* in the family *Alvernnaviridae*. The virion is icosahedral, approximately 30 nm in diameter, harbouring an ssRNA genome of around 4.4 kb in length, and is propagated in the host cytoplasm, often forming a crystalline array. Its genome is a linear positive-sense ssRNA, lacking 5'-cap structure and 3'-polyA tail, and has a stem-loop structure at the 3'-end. HcRNAV clones can be roughly divided into two types (types UA and CY) based on their intraspecies host specificity patterns; each type shows its own strain-specific infectivity that is complementary to each other. These two HcRNAV types can coexist in natural water. Typical HcRNAV clones of type UA and CY (HcRNAV34 and 109, respectively) were fully sequenced (DDBJ accession numbers: AB218608 and AB218609, respectively); they are approximately 97% identical at the nucleotide sequence level. Each genome has two open reading frames (ORFs). ORF-1 encodes a putative polyprotein having at least the serine protease domain and the RdRP domain. In about a half of the tested virus clones, a specific 15-nt deletion was found; however, it is not related in the determination of intraspecies host specificity. ORF-2 coding for the single major capsid protein (MCP) is unlikely to be a polyprotein gene because the molecular mass directly estimated by SDS polyacrylamide gel electrophoresis agrees well with the value predicted by the deduced amino acid sequence of ORF-2. Between the two virus clones tested, the stem-loop structures at the 3'-end are different in stem length and loop-size; this may affect their replication efficiency.

Similarity analysis for the deduced amino acid sequences of RdRP revealed that HcRNAV is evolutionarily quite distant from any of the land and aquatic viruses that have been genetically studied. This is also supported by a phylogenetic analysis of the RdRP amino acid sequence.

Genomic comparison revealed that complementary host ranges of HcRNAV may be related to the amino acid substitution patterns in ORF-2, within the MCP-encoding gene. In addition, the tertiary structure of the MCPs predicted by using computer modelling indicated that many of the amino acid substitutions were located in regions on the outer portion of the viral capsid proteins exposed to the ambient water environments. This suggests that the intraspecies host specificity of HcRNAV is determined by nano-structural differences of the viral surface, which may affect its binding affinity to the host cell.

By a cross-reactivity test, *H. circularisquama* clones are also divided into two types according to the sensitivity spectra of the two HcRNAV types; however, the two host types are indistinguishable when their morphology or the sequences of the internal spacer regions of the ribosomal RNA genes are compared. There are at least two distinct and independent host/virus systems between *H. circularisquama* and HcRNAV; i.e., multiple types of host and virus systems coexist within natural blooms of *H. circularisquama* and their combinations are regulated by exquisite molecular mechanisms.

Algal double-stranded RNA Viruses

Genus *Mimoreovirus*

The *Micromonas pusilla* reovirus (MpRV, originally termed as MpRNAV) is a double-stranded (ds) RNA virus infecting the cosmopolitan prasinophyte, *M. pusilla*. The polysegmented dsRNA genome of MpRV identified it as a member of a large family, *Reoviridae*, arranging

nonenveloped viruses with segmented (9–12 linear segments) dsRNA genomes. The virus was characterized by sequence, morphological and physiochemical properties and is thus far the first and only member of the genus *Mimoreovirus*. Its genome is composed of 11 segments ranging between 741 and 5792 bp, with a total size of 25,563 bp. When isolated, the virus coexisted with a large genome-sized dsDNA virus infecting the same *M. pusilla* LAC38 strain (recently renamed as *M. commoda*; van Baren *et al.*, 2016). It has a narrow host range, a latent period of 36 h (based on a one-step lytic virus growth cycle and TEM enumeration of the virus particles), and infectivity sensitivity to temperatures $>35^{\circ}\text{C}$. Non-ionic detergents and chloroform or diethyl ether did not affect infectivity, while alcohol and acetone did.

The size of intact virus particles is 90–95 nm in diameter (based on TEM images), wherein CsCl purified capsids show a compact inner structure of 75 nm surrounded by a 15 nm outer layer of protein. The smooth surface of the 50 nm subcore particles indicate that MpRV belongs to non-turreted *Reoviridae* (subfamily *Sedoreovirinae*). Within the phylogenetic tree built with *Reoviridae* polymerase (RdRP) sequences, the branch of MpRV dissects the tree, separating the group of turreted and non-turreted viruses. As *M. pusilla* is evolutionarily older than the hosts of other members of the *Reoviridae*, the topology of the tree suggests that the branch of MpRV could be ancestral.

An interesting feature is the unusual length of segment 1 (5792 bp), encoding an outer layer protein of 1877 aa long (VP1) similar to non-turreted intact particles of other viruses. If this is indeed a transient envelope structure, MpRV would be the first of the *Reoviridae* to have acquired a constitutive additional outer coat or pseudo-envelope structure, the consequence of budding of virus particles from the cell membrane or budding into the endoplasmic reticulum during morphogenesis.

The many repeats within the V1 sequence suggest that it may have arisen from amino acid fragment duplication, followed by diversification of the sequence. The mechanism and the constraints which have driven such an evolution are not clear, although very recently a model of stem-loop formation (based on the crystal structure of the polymerase of a mammalian orthoreovirus) was proposed for explaining such duplications.

Algal single-stranded DNA Viruses

Genus *Bacilladnavirus*

Diatoms are important for marine primary production and for support of coastal fisheries. To date, approximately 20 viruses capable of infecting diatoms, including *Centric* and *Pennate* genera have been isolated and characterized. Diatom viruses are divided into two groups based on their genome conformation: single-stranded (ss) RNA or ssDNA viruses. Those harbouring ssRNA are now classified in the genus *Bacillarnavirus* within the family *Marnaviridae*. Diatom-infecting viruses which harbour ssDNA belong to “genus *Bacilladnavirus*”.

The virions of bacilladnaviruses are icosahedral, 32–38 nm in diameter and accumulate in the host nucleus (Fig. 1). In addition to icosahedral virions, fibrous or rod-shaped structures, 17–27 nm in width and $>0.5\ \mu\text{m}$ in length, are often observed in diatom nuclei infected with bacilladnaviruses. The infectivity and role of the rod-shaped particles are still unknown. The ssDNA diatom virus genome is primarily a 5–6 kb, covalently closed, circular ssDNA with a $<1\ \text{kb}$ linear, complementary strand. An exception is CsetDNAV (*Chaetoceros setoensis* DNA virus), which infects the bloom-forming diatom *C. setoensis*. The CsetDNAV genome is composed of a covalently closed circular ssDNA and eight short complementary fragments (67–145 nt in length). The genome of bacilladnaviruses possesses at least two major open reading frames (ORFs) encoding a putative replication-related protein and structural proteins. The replication proteins of bacilladnaviruses display a low similarity to those of circoviruses. Their infection is highly species-specific and strain-specific. As mentioned above, they are also considered to have a significant impact on the ecology of their host populations.

Fig. 1 Transmission electron micrograph of an ultra-thin section of *Chaetoceros setoensis* host strain, NIES-3712, 48 h after CsetDNAV inoculation. Virus-like particles (V, approximately 33 nm in diameter) are accumulated in the host nucleus (N). ‘m’ indicates mitochondrion. Photographed by Y. Tomaru.

Fig. 2 Field emission SEM images of HcDNAV particles; pentagonal (A) and hexagonal projection (B), and the viroplasm of HcDNAV-infected host *Heterocapsa circularisquama* (C, D). Note that many virus particles do not completely form icosahedral shapes in the viroplasm (i.e., they have deformed shapes), but are equipped with protrusions at the vertex position, and that fibrous materials (arrowheads) are also present. Reproduced from Takano, Y., Tomaru, Y., Nagasaki, K., 2018. Visualization of a dinoflagellate-infecting virus HcDNAV and its infection process. *Viruses* 10, 554.

Algal double-stranded DNA Viruses (not Belonging to Either of the Families: *Phycodnaviridae* or *Mimiviridae*)

Genus *Dinodnavirus*

Heterocapsa circularisquama DNA virus (HcDNAV) is a dsDNA virus infecting the bloom-forming dinoflagellate, *H. circularisquama*, which is a type species of the genus *Dinodnavirus*. The virion is icosahedral and around 200 nm in diameter; each five-fold vertex is decorated with a protrusion (Fig. 2). As well as HcRNAV mentioned above, HcDNAV is reported to play a significant role in the disintegration process of *H. circularisquama* blooms. HcDNAV has a large icosahedral capsid (180–210 nm in diameter) and its genome size is estimated to be approximately 356 kbp in length. During its multiplication process, virions emerge from a specific cytoplasm compartment, called “viroplasm,” or “virus factory,” which is induced during infection by the virus (Fig. 2).

HcDNAV PolB sequence is closely related to the PolB sequence of asfaviruses with dsDNA genomes, exemplified by African swine fever virus. In addition, the amino acid sequence of HcDNAV PolB showed a rare amino acid substitution within a sequence containing a highly conserved motif.

This is an update of J.L. Van Etten, M.V. Graves, Phycodnaviruses, In Encyclopedia of Virology (Third Edition), edited by Brian W.J. Mahy and Marc H.V. Van Regenmortel, Elsevier Ltd., 2008, doi:10.1016/B978-012374410-4.00571-9.

History

The concept that viruses might have a major impact on the marine environment began almost 30 years ago with the discovery that seawater contains around 10^{10} viruses per liter. At any one time, 20%–40% of the photosynthetic microorganisms in the ocean are infected with a virus. Consequently, these viruses contribute to microbial composition and diversity, nutrient cycling, carbon flow, and other biogeochemically-important processes in aqueous environments. This huge viral population consists of both bacterial and algal viruses and they are important because phytoplankton, consisting of cyanobacteria and eukaryotic algae, fix about half of the global carbon dioxide.

Beginning in the early 1970s, viruses or virus-like particles (VLPs) have been reported in many taxa of eukaryotic algae. However, most of the early reports described single accounts of microscopic observations. This situation changed in the 1980s with the discovery of a family of large double-stranded (ds) DNA-containing viruses (referred to as chloroviruses) that infect and replicate in certain strains of unicellular, eukaryotic, symbiotic, chlorella-like green algae; these symbiotic algae are often referred to as zoochlorellae. Known chlorovirus hosts are either associated with the protozoan *Paramecium bursaria* (Fig. 1(A)), the coelenterate *Hydra viridis* or the heliozoae *Acanthocystis turfacea*. Zoochlorellae are resistant to viruses in their symbiotic state. Fortunately, the zoochlorellae from *P. bursaria*, as well as those from *A. turfacea*, can be grown independently in culture, and these cultured, naturally endosymbiotic algae serve as hosts for many large dsDNA viruses. The lytic chloroviruses can be produced in large quantities and assayed by plaque formation (Fig. 1(B)) using standard bacteriophage techniques. The prototype chlorovirus is *Paramecium bursaria chlorella virus 1* (PBCV-1).

Large polyhedral, dsDNA-containing viruses that infect marine algae are also ubiquitous throughout the world. These include viruses that infect the unicellular coccolithophore *Emiliania huxleyi* (EhV viruses, genus *Coccolithovirus*) and the other bloom-forming haptophyte *Phaeocystis globosa* (PgV viruses, genus *Prymnesiovirus*), the noxious bloom-forming raphidopyte *Heterosigma akashiwo* (HaV viruses, genus *Raphidovirus*), viruses that infect filamentous brown algae, e.g., *Ectocarpus* sp. (EsV viruses, genus *Phaeovirus*) and prasinoviruses (genus *Prasinovirus*) that infect the smallest eukaryotic cell, *Ostreococcus* and related species in the class *Mamiellophyceae*. Prasinoviruses infecting *Micromonas* were first reported in 1979 in samples of coastal seawater from British Columbia. However, more *Micromonas* viruses were not discovered until the 1990s, which led to the appreciation of their large diversity. The genomic sequence of the first prasinovirus, *Ostreococcus tauri* virus 5 (OtV5), was published in 2008. Subsequently, other viruses infecting *Ostreococcus* sp. have been sequenced, and the genomes of viruses infecting the genera *Bathycoccus* and *Micromonas* were analyzed. Now many genomes from the genus *Prasinovirus* have been sequenced, and their worldwide diversity and abundance is well documented.

Although all the phycodnaviruses probably arose from a common ancestor, they can have different lifestyles. For example, phaeoviruses have a lysogenic phase in their life-cycle (which is rare among algal viruses); the virus particles are only seen in sporangial cells of their host. Moreover, phaeoviruses also infect the giant kelp seaweed that separated from *Ectocarpus* brown algae (genus *Ectocarpus*) around 90 million years ago, further confirming the ancient evolutionary history of algal viruses.

Because the first algal viruses discovered were large dsDNA viruses, it was initially assumed that algae were only infected by large dsDNA viruses. However, this perception has changed and algal viruses with single-stranded (ss)RNA-, dsRNA- and ssDNA genomes have been discovered in the past two decades. These more recently discovered algal viruses are described in other articles in this 4th Edition of Encyclopedia of Virology entitled “Other algal viruses” and “Marnaviruses (*Marnaviridae*).”

Taxonomy and Classification

Members of the family *Phycodnaviridae* constitute a large genetically and morphologically diverse group of viruses with eukaryotic algal hosts from both inland and marine waters. Accumulating genetic evidence indicates that the phycodnaviruses together with the poxviruses, iridoviruses, asfarviruses, ascoviruses, mimiviruses, marseilleviruses, pithoviruses, molliviruses, faustoviruses and possibly pandoraviruses have a common evolutionary ancestor, perhaps, arising at the point of eukaryogenesis 3 billion or more

Fig. 1 Chlorella cells and chlorovirus PBCV-1. (A) *Parmecium bursaria* and its symbiotic chlorella cells. (B) Plaques formed by PBCV-1 on a lawn of *Chlorella variabilis* NC64A. (C) Five-fold averaged cryo-electron micrograph of PBCV-1 reveals a long narrow cylindrical spike structure at one vertex and fibers extending from one unique capsomer per trisymmetron. Note both DNA containing (dark centers) and empty capsids. (I) A model depicting PBCV-1 assembly into infectious particles including generation of the internal lipid membrane. (J) Localized lysis of cell plasma membrane and cell wall and release of progeny viruses at 8 h PI. This figure is modified with permission. (A)–(F) and (H)–(J) are modified from Van Etten, J.L., Dunigan, D.D., 2016. Giant chloroviruses – Five easy questions. *PLoS Pathogens* 12, e1005751, and (G) is modified from Milrot, E., *et al.*, 2017. *PLoS Path.* 13, e1006562, with permission.

years ago. Collectively, these large dsDNA viruses are referred to as nucleocytoplasmic large DNA viruses (NCLDV) and it has been proposed that these viruses should be included in a new order named *Megavirales*.

Phylogenetic analyses of B-type DNA polymerases encoded by all members of the *Phycodnaviridae* indicate that they are more closely related to each other than to other large dsDNA viruses and that they form a monophyletic group, consistent with a common ancestor. The phycodnaviruses fall into six clades based on phenotypic characteristics and host species and were originally given genus status. Often, the genera can be distinguished by additional properties, e.g., lytic versus lysogenic life styles or linear versus circular genomes. Among viruses with known host species, members of the genus *Chlorovirus* infect fresh water algae; however, chlorovirus DNA sequences are often reported in metagenomic studies from the ocean, which suggests that at least some chloroviruses infect marine algae or some other marine organism(s). In contrast, members of the other five genera currently listed in the International Committee on the Taxonomy of Viruses (ICTV) database (*Coccolithovirus*, *Phaeovirus*, *Prasinovirus*, *Prymnesiovirus*, and *Raphidovirus*) infect marine algae, although DNA sequences from inland water sources indicate that prasinoviruses also exist in inland water.

Complicating the taxonomy of the *Phycodnaviridae* is the fact that genomic sequencing of several recently isolated large dsDNA algal viruses indicates that they are more closely related to viruses in the family *Mimiviridae* than they are to the *Phycodnaviridae*. The largest viruses listed in the genus *Prymnesiovirus* (PgV group I viruses) belong to the *Mimiviridae* family and so these viruses have been removed from this article. However, the PgV group II viruses will probably remain in the *Phycodnaviridae* family and so they are included in this article. In addition, a couple of viruses that infect prasinophytes also belong in the *Mimiviridae* family. These mimivirus-like viruses are described in another article in this 4th Edition of the Encyclopedia of Viruses entitled “Algal viruses belonging to a subgroup within the *Mimiviridae* family.” However, the majority of the viruses that infect prasinophytes belong in the *Phycodnaviridae* and so these members remain in this article. [Table 1](#) lists representative viruses from the six genera in the *Phycodnaviridae*. Another complication is that the predicted amino acid sequences between homologous genes coded by many viruses, now classified as belonging to the same genus, can differ significantly and we expect that these genera will eventually be given family status and that many of the individual viruses will be given genus status.

Virion Structure and Composition

Morphology

Originally, all phycodnaviruses were assumed to be large icosahedral structures (100–220 nm in diameter) with a multi-laminate shell surrounding an internal membrane enclosing an electron dense core. However, recent experiments indicate that not all

Table 1 Representative members of the *Phycodnaviridae*

Genera	Type	Representative	Genome sizes	Number of CDSs
Chloroviruses	NC64A viruses	PBCV-1	330 kb	416
	SAG viruses	ATCV-1	288 kb	329
	Pbi viruses	MT325	325 kb	331
	Osy viruses	Osy-NE5	327 kb	357
	Hydra viruses	HVCV-1	300 kb	unknown
Coccolithoviruses	Emiliana huxleyi viruses	EhV-86	407 kb	472
Phaeoviruses	Ectocarpus viruses	EsV-1	336 kb	231
	Feldmannia viruses	FsV	155 kb	150
	Hicksia viruses	HincV-1	240 kb	unknown
	Myriotrichia viruses	Mclav-1	320 kb	unknown
	Pilayella viruses	PlitV-1	280 kb	unknown
	Laminaria digitata viruses	Ldif	unknown	unknown
	Micromonas viruses	MpV1	184 kb	244
Prasinoviruses	Ostrococcus viruses	OtV1	192 kb	232
	Bathycoccus viruses	BpV1	199 kb	203
Rhaphidoviruses	Heterosigma akashiwo viruses	HaV	275 kb	246
Pymnesioviruses	Phaeocystis globosa group II viruses	PgV II	unknown	unknown

phycodnavirus structures are identical. For example, fivefold-symmetry averaging 3D reconstructions revealed that one of the vertices in the chlorovirus PBCV-1 has a spike-structure (Fig. 1(C)). External fibers also extend from one capsomer in each of the 66 trisymmetron capsomes of PBCV-1 that facilitate attachment to the host (Fig. 1(D)).

Coccolithoviruses and phaeoviruses are reported to have an external membrane in addition to an internal membrane. It is thought that these viruses utilize an animal-like virus infection strategy by entering their hosts via either an endocytotic or an envelope fusion mechanism. The capsid is then disrupted and the viral DNA is transferred to the nucleus of their hosts. During the formation of these viruses, they acquire their external membrane by budding through the host plasma membrane.

Physicochemical and Physical Properties

The Mr of PBCV-1 is $\sim 1 \times 10^9$ daltons and the $S_{20,w}$ is > 2000 S. Some chlorovirus particles are disrupted in CsCl and by freeze-thawing. Chloroviruses are generally stable in sucrose but if not, they are stable in iodixanol. Non-ionic detergents do not affect infectivity, whereas organic solvents do.

The MpoV prasinoviruses, infecting *Micromonas polaris*, are isolated on temperate and Arctic host strains. Temperate MpVs (infecting *M. pusilla* and *M. commode*) remain infectious after freezing, whereas the Arctic MpoVs are sensitive to low temperature. Some prasinoviruses do not survive freezing-thawing in seawater as such, but do survive if a cryoprotectant such as 10% glycerol or dimethyl sulfoxide is added. The Arctic MpoVs are highly sensitive to temperature shifts (0–7°C) comparable to that found during a season or with depth. MpoV-45T has highest infectivity at 3°C with over an 80% drop at lower and higher temperatures, whereas MpoV-46T has the same dynamics but with optimal infectivity at 0°C. The infectivity of MpoV-44T is highest at 7°C while that of MoV-47T is largely independent of temperature.

Nucleic Acids

The viruses currently listed in the ICTV as members of the *Phycodnaviridae* contain dsDNA genomes, ranging from 170 to ~ 560 kbp. However, as noted above some of the viruses with the largest genomes will eventually be transferred to the *Mimiviridae* family. Therefore a more realistic size for the genomes in the *Phycodnaviridae* family range from ~ 100 to 440 kbp. The G + C content of the phycodnavirus genomes ranges from 30% to 55%. Chlorovirus genomes contain methylated bases, both 5-methylcytosine (5mC) and N⁶-methyladenine (6mA). The percentage of methylated bases in chloroviruses ranges from 0.1% 5mC and no 6mA to 47% 5mC and 37% 6mA. The methylation status of the genomes of other algal viruses is unknown.

Proteins

The chlorovirus PBCV-1 virion has 148 different virus-encoded proteins and at least one host-encoded protein ranging in size from < 10 to > 200 kDa. PBCV-1 has many predicted membrane proteins and multiple capsid-like proteins (CP). In addition, the PBCV-1 virion has three glycoproteins, at least two myristylated proteins and several phosphoproteins. The PBCV-1 major CP, Vp54, consists of two eight-stranded, antiparallel- β barrel, “jelly-roll” domains connected by an α helix. A recent 3.5 Å resolution structure of the PBCV-1 virion identified 14 minor proteins associated with the virion structure.

Proteomic analysis of coccolithovirus EhV-86 indicated that it is composed of at least 28 virus-encoded proteins, 23 of which are predicted to be membrane proteins, one major CP, two lectin-binding proteins, a thioredoxin and a Ser/Thr protein kinase.

Lipids

The PBCV-1 virion contains 5%–10% lipid. The lipid is located in a single bilayered membrane located inside the glycoprotein shell and is required for virus infectivity. The coccolithovirus EhV-86 has an external lipid membrane and it probably also has an internal membrane. Glycosphingolipids (GSLs) comprise more than 80% of the EhV-86 lipidome.

Many of the prasinoviruses, including the Arctic MpoVs (infecting *Micromonas polaris*), are sensitive to chloroform, which suggests that they probably have a lipid membrane. However, other MpV isolates do not lose their infectivity after treatment with chloroform. Prasinovirus MpV-08T, infecting the temperate *Micromonas*, also contains a lipid membrane, which is enriched in intact polar lipids (IPLs) in comparison with its host (e.g., the proportion of phosphatidylglycerols was greatly reduced). Other IPLs were only found in MpV (i.e., digalactosyldiacylglycerol, sulfoquinovosyldiacylglycerol and diacylglycerylhydroxymethyltrimethyl-alanine), implying that these are produced by altering IPL-bound fatty acids during viral replication.

Carbohydrates

At least three of the chlorovirus PBCV-1 proteins are glycosylated including the major CP Vp54. Vp54 has four Asn-linked glycans, which are unusual in many aspects: (1) the glycans are attached to Asn by a β -glucose linkage, which is rare in nature; (2) the asparagines are not located in the typical Asn-X-Thr/Ser consensus sequon; (3) the glycans are highly branched and consist of 9–10 neutral monosaccharides; (4) all four glycoforms contain a dimethylated rhamnose as the capping residue of the main chain, a hyper-branched fucose residue and two rhamnose residues with opposite absolute configurations; and (5) these glycans do not resemble any structures previously reported in the three Domains of Life. Unlike other glycoprotein-containing viruses, PBCV-1 encodes most, if not all, of the machinery required to glycosylate its major CP.

Genomes

Many complete or nearly complete draft genome sequences are currently available for members of the *Phycodnaviridae*, including about 45 chloroviruses, 14 coccolithoviruses, 4 phaeoviruses and 19 prasinoviruses. There is considerable variation in genome structure among members of the *Phycodnaviridae*.

The chloroviruses have linear and nonpermuted genomes that are 290–370 kb in length, which code for 330–416 predicted proteins (coding sequences, CDSs). However, in total ~640 unique CDSs are predicted to be coded by 41 chloroviruses and because any one virus encodes no more than 416 CDSs, the chloroviruses exhibit extensive genetic diversity. Furthermore, some of the chlorovirus genes encode proteins with as many as 3 distinct domains that serve different functions, which contributes to their genetic diversity. Therefore, the genetic information coded by the chloroviruses is larger than the number of genes.

The termini of the 331 kb chlorovirus PBCV-1 genome consist of 35 nucleotide-long covalently closed hairpin loops that exist in one of two forms (flip and flop); the two forms are complementary when the 35-nucleotide sequences are inverted. Each hairpin loop is followed by an identical 2.2 kb inverted repeat sequence; the remainder of the genome consists primarily of single-copy DNA. The PBCV-1 genome has 416 CDSs that have 40 or more codons. Many of the core protein genes are in conserved clusters and are referred to as gene gangs. The coding regions of some of the genes slightly overlap and early and late genes are dispersed throughout the PBCV-1 genome, although there is some clustering of the early virus genes. The CDSs are evenly distributed on both strands and intergenic space is minimal. One exception is a 1788 bp sequence near the middle of the genome, which is a polycistronic gene containing 11 tRNAs.

Marine prasinoviruses with known host unicellular green algal species in the class *Mamiellophyceae* have G + C contents that range from 35% to 50% with 203–269 compactly arranged CDSs (with an average intergenic distance of about 40 bp), 4–11 tRNAs, and terminal inverted repeats of 250 to 2150 bp. Among these prasinoviruses, viruses infecting *Bathycoccus* sp. have the fewest CDSs, but they each encode 2 very large predicted proteins (ranging from 3126 to 5689 amino acids) of unknown function that make up to 14% of the genome. About half of the sequenced *Ostreococcus lucimarinus* viruses carry a central inversion of 32 kbp. Remarkably, the overall diversity of predicted proteins in marine prasinoviruses is less than that observed between the genomes of their host genera, suggesting that these viruses may have evolved by host-switching, a hypothesis supported by the incongruence of host and viral phylogenies. Four genomes of freshwater viruses resembling prasinoviruses both in their genome structures and their phylogenetic positioning (but with unknown host species), have been assembled from metagenomic samples taken from lakes in North America and a coastal lake in China. They have genomes of 171–181 kb encoding 225–248 predicted CDSs.

Members of the genus *Coccolithovirus* have large dsDNA genomes (376–421 kbp), 444–548 predicted CDSs, and a G + C content of 40%. These viruses also encode up to 6 tRNAs and the middle of their genomes is characterized by a large section of repeats, inversions and insertions. Complete genome and DNA polymerase-based phylogenetic analyses cluster EhV isolates into distinct sub-clades, based on geographical region and time of isolation. Importantly, EhVs harbor genes for a near-complete sphingolipid biosynthesis pathway, which are homologous to those found in the host genome (see below). Although most of the predicted EhV genes have no assigned function, and most resemble genes in the Domain Eukarya (and by extension, their unicellular algal host), more than 15% are most similar to bacterial genes.

The definitive structure of the 335 kbp phaeovirus EsV genome is unknown. Several experiments suggested that the genome is circular; however, DNA sequencing indicates that it has defined ends with inverted repeats. The virus is predicted to encode 231 CDSs, 48% of which resemble proteins in the public databases. About 12% of the EsV genome consists of tandem repeats and

portions of the genome have ssDNA regions. The genome of the HaV53 strain (274,793-bp in length) contains 246 CDSs and 3 tRNA-coding sequences.

Virus Replication

Chlorovirus PBCV-1 attaches rapidly and specifically to the external surface of cell walls, but not to protoplasts, of its host *Chlorella variabilis* NC64A. The PBCV-1 virion spike structure makes the first contact with the host cell wall (Fig. 1(F)). The virus spike is too narrow to deliver DNA and likely serves to puncture the wall before it is jettisoned. Following host cell wall degradation by a virus-associated enzyme(s) (Fig. 1(G)), the virus internal membrane fuses with the host membrane, forming a membrane-lined tunnel between the virus and the host (Fig. 1(H)), and leaving an empty capsid attached to the surface. Interestingly, the membrane-lined tunnel between the virus and host is so narrow that the compressed DNA (ca. 0.2 bp nm⁻³) in the virion must pass into the host in a linear manner and then once inside the host it appears to condense again. The virus-host membrane fusion process triggers rapid depolarization of the host plasma membrane, probably initiated by a virus encoded K⁺ channel located in the virus internal membrane. This hypothesis is supported by the fact that infection by the chloroviruses is inhibited by the K⁺ channel blockers barium and/or cesium. The depolarization results in the release of K⁺ from the cell. This rapid loss of K⁺ from the host and associated water fluxes reduce the host turgor pressure, which aids ejection of viral DNA and virion-associated proteins into the host. Host membrane depolarization also inhibits many host secondary transporters and prevents infection by a second virus.

None of the chloroviruses encode a recognizable DNA-dependent RNA polymerase (DdRp) gene, so it is assumed that PBCV-1 DNA and viral-associated proteins quickly move to the nucleus and commandeer the host transcription machinery. Early transcription begins 5–10 min post-infection (PI). Viral DNA synthesis begins at 60–90 min PI and presumably starts in the nucleus before moving to the cytoplasm. At 3–4 h PI, assembly of PBCV-1 capsomers begins in localized regions of the cytoplasm, which become prominent 4–5 h PI (Fig. 1(H)). These localized regions, called virus assembly centers or virus factories, consist of host cisternae that are derived from the endoplasmic reticulum next to the nuclear membrane (Fig. 1(I)). The cisternae are localized at the periphery of the viral assembly centers and are cleaved into single bilayered membranes, which then move to the central region of the assembly centers. Capsomers form around these membranes leading to the formation of empty virions at the periphery of the virus assembly centers where DNA packaging occurs. By 5–6 h PI the cytoplasm fills with infectious progeny viruses and localized lysis of the host cell membrane and cell wall releases progeny at 6–8 h PI (Fig. 1(J)). Each infected algal cell releases ~1000 newly formed virus particles, of which ~25% form plaques. Mechanical disruption of cells releases infectious virus particles 30–50 min prior to cell lysis, indicating the virus is mature and does not acquire its glycoprotein capsid by budding through the host plasma membrane as it is released from the cell.

The coccolithovirus EhV virion has an external lipid membrane and the virus encodes 6 RNA polymerase subunits, none of which are packaged in the virion. EhV enters the host cell via either endocytosis or an envelope fusion mechanism by interacting with lipid rafts on the host membrane, which are used as focal points for attachment and entry. Upon entry, EhV internalization and breakdown of the virion capsid takes place instantaneously, quickly followed by the release of the virion genome into the nucleus. There, early virus transcription occurs using host RNA polymerases, followed by transcription of the rest of the viral genes in the cytoplasm, where capsid assembly and viral DNA synthesis occurs. The newly assembled viruses are transported to the plasma membrane where they acquire the inner lipid layer by association with intracellular lipid bodies, and they are released from the cell by budding through lipid rafts where they acquire a GSL rich outer membrane. A large proportion of newly-formed viruses are also released by eventually lysing the host cell.

The EhV latent period can be as short as 4–8 h PI and EhV burst sizes range from 50 to 1000 new particles per lysed cell. The number of infectious EhV progeny can be as high as 30% or as low as 1%, depending on the type of EhV and host (e.g., calcifying or not). Prymnesioviruses and prasinoviruses have somewhat longer latent periods than the coccolithoviruses. Burst size for the prymnesioviruses is between 275 and 410 and up to 330 per lysed host cell for prasinovirus MpV.

Host responses to EhV infection are diverse and can often be used as early markers of infection. For example, EhV infection triggers a series of metabolic events, including host lipid and fatty acid remodeling that includes the production of viral encoded GSLs that are essential for infection, differential induction of nitric oxide and reactive oxygen species, induction of caspase activity, enhanced metacaspase expression, activation of program cell death and autophagy pathways, and impairment of the host photosystem apparatus. Furthermore, EhV infection results in the excess production of “sticky” extracellular polysaccharides, which are exuded from infected cells and facilitate aggregation of cellular content and debris into larger organic carbon-containing particles.

Phaeovirus EsV initiates its life-cycle by infecting free-swimming, wall-less gametes of its host. Virus particles enter the cell by fusion with the host plasma membrane and release a nucleoprotein core particle into the cytoplasm, leaving remnants of the capsid on the surface. The viral core moves to the nucleus within 5 min PI. One important feature that distinguishes the EsV life-cycle from the other phycodnaviruses is that the viral DNA becomes integrated into the host genome and is transmitted mitotically to all cells of the developing alga. The viral genome remains latent in vegetative cells until it is expressed in the algal reproductive cells, the sporangia or gametangia. Massive viral DNA replication occurs in the nuclei of these reproductive cells, followed by nuclear breakdown and viral assembly that continues until the cell becomes densely packed with virus particles. Virus release is stimulated by the same factors that induce discharge of gametes from the host, i.e., changes in temperature, light, and water composition. This synchronization facilitates interaction of viruses with their susceptible host cells.

Less is known about replication of the prasinoviruses and raphidoviruses, although formation of the raphidovirus HaV occurs in the cytoplasm and the nucleus remains intact and separate from the viroplasm that consists of a fibrillar matrix. Ultimately, viral production results in the disruption of organelles, lysis of the cell and release of the virus particles. Unlike the chloroviruses, which are very host specific, some of the raphidoviruses can infect a range of host isolates within specific algal species; however, there is no evidence that they cross the species barrier.

Virus Transcription

After entry of the chlorovirus PBCV-1 DNA into the cell its DNA and viral-associated proteins quickly move to the nucleus and commandeer the host transcription machinery. Early transcription of PBCV-1 begins 5–10 min PI. In this immediate-early phase of infection, host transcription rates decrease and the host transcription machinery is reprogrammed to transcribe viral DNA. Some early viral transcripts are synthesized in the absence of protein synthesis. Details of reprogramming are unknown but host chromatin remodeling is probably involved because PBCV-1 encodes and packages an enzyme that methylates Lys-27 in histone 3. Circumstantial evidence indicates that this methylation represses host transcription following PBCV-1 infection. In addition, host chromosomal DNA degradation begins within 5 min PI, presumably by PBCV-1 encoded and packaged DNA restriction endonucleases, which also aids in inhibition of host transcription and release of the host transcription machinery for the benefit of the virus.

PBCV-1 dominates the infected cells in the early phase prior to initiation of viral DNA synthesis, which begins at 60–90 min PI. Microarray experiments indicated that 63% of the PBCV-1 genes are expressed early, whereas late genes are expressed (after 60 min PI) until the end of virus replication; 43% of the genes are expressed both early and late. Remarkably, an RNA-seq based transcription profile revealed that ~50 PBCV-1 genes are expressed within the first 7 min PI. By 60 min PI, essentially all of the PBCV-1 genes are expressed at some level and ~40% of the poly (A +) containing RNAs in the infected cell are PBCV-1 transcripts. As expected, the synthesis of late transcripts requires translation of early virus genes.

Consensus promoter regions for early and late PBCV-1 genes have not been identified definitively; however, the sequence AATGACA is common in the 100 nucleotides preceding the ATG start codon of most early PBCV-1 genes. Furthermore, the 50 nucleotides preceding the ATG start codons are usually >70% A + T. Transcription of some PBCV-1 genes appears to be complex. For example, some gene transcripts exist as multiple bands and these patterns can change between early and late times in the virus life-cycle.

Transcription of prasinovirus genomes has been analyzed by RNA-Seq in *Micromonas pusilla* infected with MpV-SP1 in continuous light or in *Ostreococcus tauri* infected with OtV5 in a 12 h day 12 h night growth regime. In both cases, the availability of complete host and viral genomes allowed the expression of all host and viral genes to be monitored over the viral life-cycles. In *M. pusilla* the continuous light experiments focused on comparing the effects of different nutrient phosphate levels, whereas in *O. tauri* a day/night cycle was used to mimic natural growth conditions because host gene expression is influenced strongly by light and the cell cycle. When *M. pusilla* growth was limited by 10-fold less phosphate, only 30% of host cells were lysed by MpV-SP1 virus at 24 h PI, compared to 70% lysis in controls; about 5.8% of the differentially regulated genes were due to the viral infection. In *O. tauri* the host cell growth was mainly synchronous, with S-phase (DNA synthesis) occurring in late afternoon-early night and cell division in early night. Under these conditions, prasinovirus transcripts were much less abundant in the day and host cell lysis occurred mainly during the following day. During the night, about 4.4% of host genes showed increased expression relative to uninfected controls, likely representing both genes de-repressed for viral virulence and induced for host defense. Practically all of MpV-SP1 and OtV5 genes were expressed during infections, except for a few CDSs residing in the terminal inverted repeat regions.

Coccolithovirus EhV transcription also begins in the host nucleus using the host DdRp even though EhV encodes 6 RNA polymerase subunits; however, none of them are packaged in the virus. Transcriptional analysis suggests that viral RNA polymerase gene expression occurs in a secondary transcriptional phase (occurring at least one hour PI and demarcated by a transition from a unique-promoter driven, locus-specific transcriptional activity to a genome wide transcriptional activity), potentially indicative of a biphasic replication cycle with both nuclear and cytoplasmic phases.

Ecology

Eukaryotic algae are important components of both inland water and marine environments; however, the significance of viruses in these systems is only beginning to be appreciated. The diversity of marine prasinoviruses was first noted by using the DNA polymerase gene found in all NCLDV as a genetic marker. Using degenerate oligonucleotide primers and subsequent sequencing revealed viruses that were likely to infect the microalga *Micromonas*. Subsequently, diverse viruses infecting the species *Ostreococcus tauri* and *Bathycoccus* sp. (also members of the algal class *Mamiellophyceae*) were identified in coastal samples from the North Sea and Mediterranean Sea. The availability of several prasinovirus genomes permitted screening of very large metagenomic datasets, such as those produced by the *Tara-Oceans* expedition, for the presence of prasinoviruses and showed them to be one of the most abundant types of NCLDV in marine waters. A new degenerate primer pair, in combination with next generation sequencing of PCR products, revealed enormous viral diversity in different marine samples. The viral diversity and distribution are dependent on environmental conditions affecting host growth, e.g., nutrient and light availability and temperature.

Controlled one-step infection experiments with prasinoviruses demonstrated that nutrient limitation typically results in longer latent periods, reduced burst sizes and delayed lysis of the host as compared to control treatments. For example, the burst size of MpV-08T was reduced by 70% under phosphate limitation as well as under nitrogen and iron limitation. *Micromonas* growth is not strongly affected by light intensity and this may be the reason that MpV proliferation is also not impaired by low or high light, independent of whether the host is phosphorus limited or not. Likely MpV proliferation is not dependent on photophosphorylation during infection, similar to chlorovirus production in *Chlorella*. Besides nutrients and light, temperature is also an important host growth-regulating variable and indeed in the Arctic it impacts MpoV viral burst size and progeny virus infectivity.

Phycodnaviruses can play major roles in the termination of marine algal blooms and research efforts are actively focusing on elucidating the natural history of these algal/virus systems. For example, EhV and PgV viruses are one of the primary mechanisms for terminating *Emiliania huxleyi* and *Phaeocystis globosa* blooms, respectively. EhV infection and replication is affected by light, and newly formed virus particles can be transmitted to surrounding regions by 'hitch-hiking' on zooplankton and by marine aerosols. Likewise, infection by the rhabdovirus HaV is regarded as one of the factors influencing the dynamics and termination of *Heterosigma akashiwo* blooms. HaV has a significant impact on *H. akashiwo* populations and changes clonal composition of the alga. Based on host-virus cross reactivity tests, HaV isolates were divided into three groups (I-III) according to their intraspecies host range.

Chloroviruses are ubiquitous in inland water collected throughout the world and titers as high as thousands of infectious particles per ml have occasionally been reported. However, typically the titer is 1–100 infectious particles per ml. The titers are seasonal with the highest titers in the spring and late fall as monitored in a lake in the temperate zone. It is not known if chloroviruses replicate exclusively in zoochlorellae symbiotic with paramecia and heliozoae or if the viruses have another host (s). In fact, it is not known if these zoochlorellae exist free of their hosts in natural environments. However, zoochlorellae contained within their symbiotic hosts are refractory to infection by chloroviruses because the viruses cannot contact the algae.

In the case of the ciliate *Paramecium bursaria*, chloroviruses can attach to the outer membrane of the paramecia without infecting them, which puts the viruses in good position to encounter zoochlorellae if the paramecium is disrupted by a feeding predator. For example, copepods feed on paramecia by engulfing them and pass viable zoochlorellae through their digestive system intact, which leads to virus infection and a rapid increase in viral titer. This gives rise to the concept of predation being an ecological catalyst. Other predators such as *Didinium* can forage on zoochlorellae-bearing paramecia and rupture the cell, which results in the release of zoochlorellae where they can be infected.

The lysogenic phaeoviruses EsV and FsV infect the small filamentous brown algae *Ectocarpus* sp and *Feldmania* sp, respectively. Lysogeny is consistent with the observation by early investigators that VLPs appeared infrequently in eukaryotic algae and only at certain stages of algal development. The apparent lack of infectivity by many of these previously observed VLPs in eukaryotic algae is also consistent with a lysogenic lifestyle. The VLPs might either infect the host and resume a lysogenic relationship or be excluded by pre-existing lysogenic viruses. The ultimate role of the viruses in the ecology of their host is still unknown.

Lysogenic phaeoviruses have also recently been reported to infect the large perennial *Laminaria* macroalgae (kelp). Kelp form underwater forests that dominate coastlines on all continents and form some of the most productive and structurally complex ecosystems in the world, which support diverse marine communities. The role that the phaeoviruses play in kelp ecology is completely unknown.

To summarize, phycodnaviruses contribute to microbial composition and diversity, nutrient cycling, carbon flow, and other bio-geochemically-important processes in aqueous environments.

Resistance to Phycodnavirus Infections

Resistance to virus infection has been studied to some degree for members of three genera within the family Phycodnaviridae. In the case of the chloroviruses, resistance to virus infection occurs quite frequently and most of the time this is due to a change in the host receptor such that the chloroviruses are unable to attach to the host.

Coccolithoviruses infect the marine microalga, *Emiliania huxleyi*. The alga has different life forms including: (1) diploid coccolith-bearing or naked, non-motile cells that are susceptible to the virus, (2) diploid coccolith-bearing or naked, non-motile cells that are resistant to the virus; and (3) haploid, non-calcifying, organic scale-bearing swarming cells that were originally reported to be resistant to virus infection. However, recent evidence indicates that virus-derived lipids are present in *E. huxleyi* haploid cells, indicating that the cells are actually infected. In addition, virus transcripts are detected in these cells in the absence of cell lysis due to virus infection. This superimposed state of being both infected and resistant is reminiscent of Schrödinger's cat; i.e., of being simultaneously both dead and alive.

In the green microalga *Ostreococcus tauri*, resistance to prasinovirus infection arises frequently in culture and in *Micromonas* sp. the frequency of spontaneous resistance is temperature-dependent. RNA-Seq transcription analysis of many independent OtV5-resistant clonal lines obtained from OtV5-infected cultures revealed overexpression of all genes spanning half of the physical length of chromosome 19, and physical rearrangements of this chromosome are also observed in karyotypic analyses of these lines. This chromosome, which carries many predicted glycosyltransferase genes, is variable in its genetic structure in different wild-type algal strains, and appears to be involved in viral defense.

Phycodnavirus Genes Encode Some Interesting and Unexpected Proteins

Many chlorovirus-encoded proteins are either the smallest or among the smallest proteins of their class. In addition, homologous genes in the chloroviruses can differ in nucleotide sequence by as much as 50%, which translates into amino acid differences of 30%–40%. Therefore, comparative protein sequence analyses can identify conserved amino acids in proteins as well as regions that tolerate amino acid changes. The small sizes and the finding that many chlorovirus-encoded proteins are 'user friendly' have resulted in the biochemical and structural characterization of many PBCV-1 encoded proteins. Examples include: (1) 5mC and 6mA DNA methyltransferases and their companion DNA site-specific endonucleases (some of which are sold commercially); (2) the smallest eukaryotic ATP-dependent DNA ligase, which is also sold commercially; (3) the smallest type II DNA topoisomerase (the virus enzyme cleaves dsDNAs ~50 times faster than the human type II DNA topoisomerase); (4) a small prolyl-4-hydroxylase that converts Pro-containing peptides into hydroxyl-Pro-containing peptides in a sequence-specific fashion; and (5) one of the smallest proteins (82 amino acids) to form a functional K^+ channel. In fact, the prasinovirus MpV-12T encodes a functional 78 amino acid K^+ channel protein. These virus-encoded K^+ channels are under intensive investigation and there are over 60 publications on them.

The chloroviruses are also unusual because they encode enzymes involved in sugar metabolism. Three PBCV-1-encoded enzymes, glutamine:fructose-6-phosphate aminotransferase, UDP-glucose dehydrogenase, and hyaluronan synthase are involved in the synthesis of hyaluronan, a linear polysaccharide composed of alternating β -1,4-glucuronic acid and β -1,3-N-acetylglucosamine residues. All three genes are transcribed early in PBCV-1 infection and hyaluronan accumulates on the external surface of the infected cells. Other chloroviruses encode a chitin synthase and chitin accumulates on the external surface of these infected cells. Two PBCV-1 encoded enzymes, GDP-D-mannose dehydratase and fucose synthase, comprise a three-step pathway that converts GDP-D-mannose to GDP-L-fucose and GDP-L-rhamnose. Both of these monosaccharides are in the glycans attached to the virus major CP. As noted earlier, PBCV-1 encodes most if not all of the machinery to glycosylate its major CP including several glycosyltransferases.

PBCV-1 is the first virus known to encode 5 functional enzymes involved in polyamine biosynthesis and catabolism including: ornithine decarboxylase (ODC), homospermidine synthase, agmatine iminohydrolase, N-carbamoyl-putrescine amidohydrolase and a polyamine acetyltransferase. ODC catalyzes the decarboxylation of ornithine to putrescine, which is the first and the rate limiting enzymatic step in polyamine biosynthesis. Not only is the PBCV-1-encoded ODC the smallest known ODC, the PBCV-1 enzyme is also interesting because it decarboxylates arginine more efficiently than ornithine. Homospermidine synthase is a virion-associated protein.

The chloroviruses also encode many other interesting and unexpected enzymes that have been characterized including an aquaglyceroporin, a Ca^{2+} transporting ATPase, a K^+ transporter, a pyrimidine dimer specific glycosylase, an aspartate transcarbamylase, and a thymidylate synthase X.

Another set of unexpected proteins is encoded by the EhV coccolithoviruses. These include enzymes that comprise a near-complete *de novo* sphingolipid biosynthesis pathway believed to have been acquired from the host via horizontal gene transfer (HGT). Importantly in eukaryotes, sphingolipids are common building blocks of membrane lipids and lipid rafts. The first, and likely rate-limiting enzyme in this pathway is serine palmitoyltransferase (SPT). Its inhibition by myriocin (a sphingosine equivalent which is a specific and effective inhibitor of SPT in yeast and mammalian cells) halts successful EhV replication in a dose dependent manner. Other putative proteins coded by the different EhVs include: a phosphate permease, polyubiquitin, and a sialidase.

In contrast to the chloroviruses, the gene content of many prasinoviruses has only come to light in the last decade and very few of the predicted gene functions have been experimentally verified. Exceptions to this are certain cation transporters, whose function has been tested by heterologous expression in yeast or mammalian cells. Some prasinoviruses encode phosphate or ammonium transporters that are thought to confer nutritional advantages to their host cells during infection. These, and numerous other genes are likely to have been acquired by HGT, either from the host or from other microbes. About 30% of the prasinovirus genes show similarity to genes with known functions, and include a diversity of interesting genes whose number increases with every new virus sequenced. All prasinoviruses encode methylases and glycosyltransferases that are likely involved in modifications of host or viral DNA or proteins important for the viral life-cycle. Many *Ostreococcus* or *Micromonas* viruses encode putative enzymes for amino acid synthesis (for example 3-dehydroquinate synthase, acetolactate synthase, oxovalerate aldolase) or sugar synthesis (for example 6-phosphofructokinase). Near-complete genomes of some prasinoviruses with unknown host species have been assembled from brackish or freshwater lakes, and encode genes for a multidrug resistance protein and for histone H3, which is likely to be involved either in host or viral gene expression and/or virus DNA packaging.

Perspectives

Eukaryotic algae are important components of both inland water and marine environments. However, the significance of viruses on host population dynamics in these systems is only beginning to be appreciated. It is obvious that identifying and characterizing large dsDNA viruses that infect eukaryotic algae is in its infancy. For example, metagenomic studies, such as DNA sequencing in the Sargasso Sea, indicate that many algal viruses exist in a variety of aqueous environments with unknown hosts. This lack of knowledge certainly carries over to soil samples. Furthermore, with a few possible exceptions, little is known about the replication

cycles of most algal viruses. The few algal-virus systems that are under investigation indicate that the various systems differ extensively, e.g., in their infection processes, in their replication cycles, consequences of infection (lytic versus lysogenic), and probably in many other aspects. The development of efficient systems that allow scientists to conduct molecular manipulations of the algal virus genomes would provide a huge boost to the study of algal viruses. Such techniques are currently lacking.

Finally, it should be noted that algal viruses encode many interesting proteins, and even some that have potential for commercial exploitation. Unfortunately, it is also true that most of the putative proteins in these viruses have unknown functions and they often have no homology to proteins in the public domain databases. Who knows how many more unexpected algal virus encoded proteins await discovery?

Acknowledgments

We want to thank all of the many researchers who have contributed to the growing field of algal virology, especially close colleagues for useful discussions, and those whose work has not been mentioned because of space limitations.

Nomenclature

BV Budded virus (baculoviruses)

G Virion glycoprotein, structural protein

gRNA Genomic (or virion) RNA

GV Granulovirus

ICTV International Committee on Taxonomy of Viruses

IRES Internal ribosome entry site on ssRNAs

L Long segment of a tripartite RNA genome

M Medium segment of a tripartite RNA genome

N Virion nucleoprotein, structural protein of core

NPV Nucleopolyhedrovirus

NS Nonstructural protein

ODV Occlusion derived virus (baculoviruses)

P Virion phosphoprotein, structural protein

RdRp RNA dependent RNA polymerase (of RNA viruses)

S Short segment of trisegmented RNA genome

sgRNA Subgenomic RNA especially for *Nidovirales* viruses

TRS Transcription regulating sequence (*Nidovirales* viruses)

+ve ssRNA positive sense (mRNA sense) single stranded RNA

–ve ssRNA antisense (anti mRNA sense) single stranded RNA

VP Virion protein

Glossary

Granulovirus It is a term used for insect baculoviruses which produce granules composed of granulin each containing a single virion and which protects the virus from the environment.

Internal ribosome entry site (IRES) It is a sequence in a mRNA which allows for cap-independent translation. This is common to the *Picornavirales* order but occurs in the RNAs of others as well.

International Committee on Taxonomy of Viruses It is an international committee which has a defined organizational structure which meets on an annual basis to review proposals on new taxonomies, or changes in taxonomies. Once proposals are formally accepted the committee updates the taxonomy and posts it to the ICTV Website at “See Relevant Websites section”.

Nucleopolyhedrovirus It is a term used for the insect baculoviruses which produce large polyhedral particles

composed of polyhedrin in which virions are embedded to protect them from the environment.

RNA dependent RNA polymerase (RdRp) It is an RNA polymerase which synthesizes RNA copies from an RNA template strand. It is an enzyme which allows an RNA virus to transcribe its genome into antigenome RNA, viral mRNA or subgenomic mRNAs.

Subgenomic RNAs (sgRNAs) They are smaller segments of RNA produced from a long RNA template with each segment encoding a different ORF, or in the case of the *Nidovirales* different combinations of ORFs.

Transcription regulating sequence (TRS) It is a short sequence in viral RNA at the beginning of the first ORF or between subsequent ORFs, especially for viruses in the *Nidovirales* order, that allow transcription of subgenomic mRNAs with each sgRNA being translated into a different ORF.

Introduction

Considering that invertebrate species outnumber the total of all other global species by about 9 to 1 and, other than bacteria, have a longer evolutionary history, it is not surprising that they harbor the majority of virus species on earth. Although most people think of invertebrates as arthropods, including insects and spiders, they also include protozoans, annelids, echinoderms and molluscs. For the sake of simplicity and acknowledging the paucity of information on viruses in other groups of invertebrates, this review will focus mostly on viruses of arthropods, specifically insects, arachnids and crustaceans and, due to their economic importance, molluscs.

While many viruses, notably the arboviruses of mammals and plants, infect both their invertebrate vectors and vertebrate or plant hosts, the rest are restricted to individual species of animals. [Table 1](#) summarizes the different species of invertebrate viruses based on the Family taxon. For the sake of simplicity names of only taxa from the Family level (and Order) and below are given. Higher orders of Class, Subphylum, Phylum, Kingdom and Realm, favored by the International Committee on the Taxonomy of Viruses (ICTV) may be of relevance to those interested in virus evolution and bioinformatics, but from a practical level have little value to most practicing virologists and are not included in these summaries. As one example for the complete taxonomy of a virus of invertebrates, the taxonomy of nonviruses would have to include all of Realm *Ribovairia*, Kingdom *Orthornavirae*, Phylum *Pisuviricota*, Subphylum none, Class *Pisonvircetes*, Order *Nidovirales*, Suborder *Ronidovirineae*, Family *Roniviridae*, Subfamily *Okanovirinae*, Genus *Okavirus*, Subgenus *Tipravirus*, Species *Gill-associated virus*. It would be too cumbersome to provide such a complete taxonomy for all viruses in this article and would probably be of little interest. Nevertheless those interested in the higher levels of classification ordained by the

Table 1 Families and Genera of Viruses Replicating in or Associated with Invertebrate Hosts

Family/Subfamily Order	Genus, Subgenus, Type Species (total # in genus)	Genome type, segments and size	Morphology, T value for icosahedral capsids	Major invertebrate host
<i>Alphatetraviridae</i> (<i>Hepelivirales</i>) ^a	<i>Betatetravirus</i> , <i>Nudaurelia capensis beta virus</i> (7) <i>Omegatetravirus</i> , <i>Nudaurelia capensis omega virus</i> (3)	Beta-monopartite, + v ssRNA, 6.6 kb Omega-bipartite 2.5/5.3	Icosahedral T=4, 42 nm diameter	lepidoptera
<i>Artoviridae</i> (<i>Mononegavirales</i>)	<i>Hexartovirus</i> , <i>Caligid hexartovirus</i> (2) <i>Peropuvirus</i> , <i>Pteromalus puparum peropuvirus</i> (6)	– ve ssRNA, monopartite, 12.5 kb	Spherical, flexuous nucleoprotein core, 100 to 130 nm enveloped	Wasps, barnacles, copepods, pill worms, woodlice, ticks
<i>Ascoviridae</i> (<i>Pimascovirales</i>)	<i>Ascovirus</i> , <i>Spodoptera frugiperda ascovirus 1a</i> (3) <i>Toursvirus</i> , <i>Diadromus pulchellus toursvirus</i> (1)	Circular dsDNA, 100 to 200 kb	Core 80 × 300 nm, enveloped 130 × 200 to 400 nm allantoid or reniform virion	Lepidoptera, parasitoid wasps
<i>Baculoviridae</i>	<i>Alphabaculovirus</i> , <i>Autographa californica multiple nucleopolyhedrovirus</i> (55) <i>Betabaculovirus</i> , <i>Cydia pomonella granulovirus</i> (26) <i>Deltabaculovirus</i> , <i>Culex nigripalpus nucleopolyhedrovirus</i> (1) <i>Gammabaculovirus</i> , <i>Neodiprion lecontei nucleopolyhedrovirus</i> (2)	Circular ds DNA, 82 to 180 kb	Budded virus helical nucleocapsids 30 to 60 nm × 250 to 300, enveloped Occlusion derived virus form (ODV) embedded in a polyhedral occlusion body NPV polyhedral 0.15 to 5.0 μM diameter GV polyhedral 0.12 to 0.5 μM diameter	Lepidoptera, hymenoptera diptera
<i>Bidnaviridae</i> (<i>Poliovirales</i>)	<i>Bidensovirus</i> , <i>Bombyx mori bidensovirus</i> (1)	Linear ssDNA, ambisense, bipartite, 6 and 6.5 kb	Icosahedral T=1, 20 to 24 nm, separate capsid for each of 4 ssRNAs	silkworm
<i>Birnaviridae</i>	<i>Entomobirnavirus</i> , <i>Drosophila X virus</i> (2)	dsRNA, bipartite, 3.2, 3.4 kb	Icosahedral T=3, 60 to 70 nm diameter	Drosophila, mosquitoes
<i>Carmotetraviridae</i> (<i>Tollivirales</i>)	<i>Alphacarmotetravirus</i> , <i>Providencia virus</i> (1)	+ ve ssRNA, monopartite, 6.2 kb	Icosahedral T=4, 40 nm diameter	lepidoptera
<i>Circoviridae</i> (<i>Cirivirales</i>)	<i>Circovirus</i> , <i>Porcine circovirus 1</i> (43) <i>Cyclovirus</i> , <i>Human associated cyclovirus 8</i> (51)	ssDNA, circular, 1.7 to 1.9 kb	Icosahedral T=1, 15 to 25 nm diameter	Cockroach, dragonfly, mosquito, ants, spiders, ticks
<i>Dicistroviridae</i> (<i>Picornavirales</i>)	<i>Aparavirus</i> , <i>Acute bee paralysis virus</i> (6) <i>Cripavirus</i> , <i>Cricket paralysis virus</i> (4) <i>Triatovirus</i> , <i>Triatoma virus</i> (5)	+ ve ssRNA, monopartite 8.0 to 10.2 kb,	Icosahedral, pseudo T=3, 30 nm diameter	Bees, ants, aphids, drosophila, triatomine bugs
<i>Genomoviridae</i> (<i>Geplafuvirales</i>)	<i>Gemycircularvirus</i> , <i>Sclerotinia gemycircularvirus 1</i> (43) <i>Gemyduguivirus</i> , <i>Dragonfly associated gemyduguivirus 1</i> (1) <i>Gemykibivirus</i> , <i>Dragonfly associated gemykibivirus 1</i> (16)	ssDNA, circular, 2.2 kb	Icosahedral T=1, 29 nm diameter	Dragonfly, mosquito
<i>Hytrosaviridae</i>	<i>Glossinavirus</i> , <i>Glossina hytrosavirus</i> (1) <i>Muscavirus</i> , <i>Musca hytrosavirus</i> (1)	dsDNA, circular, 124 to 190 kb	Rod shaped, 50 to 65 nm × 500 to 1,000 nm, helical core, enveloped	Diptera and perhaps hymenoptera
<i>Iflaviridae</i> (<i>Picornavirales</i>)	<i>Iflavirus</i> , <i>Infectious flacherie virus</i> (15)	+ ve ssRNA, linear, monopartite 8-10.5 kb, VPg at 5' end, poly A at 3' end	Icosahedral, pseudo T=3, 22 to 30 nm diameter	Honey bees, parasitic mites, lepidoptera, aphids, planthoppers
<i>Iridoviridae</i> <i>Betairidovirinae</i> (<i>Pimascovirales</i>)	<i>Chloriridovirus</i> , <i>Invertebrate iridescent virus 3</i> (5) <i>Decapodiridovirus 1</i> , <i>Decapod iridescent virus 1</i> (1) <i>Iridovirus</i> , <i>Invertebrate iridescent virus 6</i> (2)	dsDNA, linear 163 to 220 kb, circularly permuted terminally redundant, methylated	Icosahedral T=147 to 217, 150 to 200 nm diameter, inner membrane, naked or enveloped	Mosquitoes, lepidoptera, isopods, crabs, shrimp
<i>Lispiviridae</i> (<i>Mononegavirales</i>)	<i>Arlivirus</i> , <i>Lishi arlivirus</i> (6)	– ve ssRNA, linear, bisegmented, 7.1, 4.4 kb	Unknown, identified solely from sequence data	Spiders
<i>Malacoherpesviridae</i> (<i>Herpesvirales</i>)	<i>Aurivirus</i> , <i>Haliotid herpesvirus 1</i> (1) <i>Ostreavirus</i> , <i>Ostreid herpesvirus 1</i> (1)	dsDNA, linear, 134 to 212 kb	Icosahedral T=16 nucleocapsid, spherical 150 to 200 nm diameter virion, enveloped	Molluscs
<i>Mesoniviridae</i> <i>Hexponivirinae</i> (<i>Nidovirales</i>)	<i>Alphamesonivirus</i> (10) <i>Subgenus Namcalivirus</i> , <i>Alphamesonivirus 1</i> (2 species)	+ ve ssRNA, linear, monopartite, 20 kb, 5' cap 3' polyA tail	Spherical, 50 to 120 nm enveloped with spike protein	Mosquito

<i>Nimaviridae</i>	<i>Whispovirus</i> , <i>White spot syndrome virus</i> (1)	dsDNA, circular, 280 to 307 kb	Ellipsoid, nucleocapsid 70 to 170 nm × 210 to 420 nm, with tegument and envelope	Crustaceans, shrimp
<i>Nodaviridae</i> (<i>Nodamuvirales</i>)	<i>Alphanodavirus</i> , <i>Nodamura virus</i> (5)	+ ve RNA, linear, bipartite, 1.4 and 3.1 kb	Icosahedral T=3, 25 to 33 nm diameter	coleoptera
<i>Nudiviridae</i>	<i>Alphnudivirus</i> , <i>Oryctes rhinoceros nudivirus</i> (2) <i>Betanudivirus</i> , <i>Heliothis zea nudivirus</i> (1)	dsDNA, circular, 96 to 232 kb	Nucleocapsid rod-shaped helical core, enveloped virus 81 to 100 × 200 to 415 nm	Beetles, lepidoptera, crustaceans
<i>Nyamiviridae</i> (<i>Mononegavirales</i>)	<i>Berhavirus</i> , <i>Sipunculid berhavirus</i> (3) <i>Crustavirus</i> , <i>Wenzhou crustavirus</i> (3) <i>Nyavirus</i> , <i>Nyamanini nyavirus</i> (3) <i>Orinovirus</i> , <i>Orinoco orinovirus</i> (1) <i>Socyvirus</i> , <i>Soybean cyst nematode socyvirus</i> (1) <i>Tapwovirus</i> , <i>Tapeworm tapwovirus</i> (1)	– ve ssRNA, linear, monopartite, 12.2 kb (bipartite for <i>Tapwovirus</i>)	Enveloped spherical particles, 100 to 130 nm diameter	Ticks, insects, echinoderms, spiniculids, crustaceans, nematodes, tapeworms (land and sea birds)
<i>Parvoviridae</i> <i>Densovirinae</i> (<i>Piccovirales</i>)	<i>Aquambidensovirus</i> , <i>Decapod aquambidensovirus</i> 1 (2) <i>Blattambidensovirus</i> , <i>Blattella blattambidensovirus</i> 1 (1) <i>Hemiambidensovirus</i> , <i>Hemipteran hemiambidensovirus</i> 1 (2) <i>Iteradensovirus</i> , <i>Lepidopteran iteradensovirus</i> 1 (5) <i>Miniambidensovirus</i> , <i>Orthopteran miniambidensovirus</i> 1 (1) <i>Pefuambidensovirus</i> , <i>Blattodean pefuambidensovirus</i> 1 (1) <i>Protoambidensovirus</i> , <i>Lepidopteran protoambidensovirus</i> 1 (2) <i>Scindoambidensovirus</i> , <i>Orthopteran scindoambidensovirus</i> 1 (3)	ssDNA, linear 4 to 6 kb	Icosahedral T=1, 21 to 28 nm diameter	Crickets, crayfish, Hymenoptera, Orthoptera, Hemiptera, Lepitoptera, aphids, crustaceans, mosquitoes, echinoderms, prawns
<i>Parvoviridae</i> <i>Hamaparovirinae</i> (<i>Piccovirales</i>)	<i>Brevihamaparvovirus</i> , <i>Dipteran brevihamaparvovirus</i> 1 (2) <i>Hepanhamaparvovirus</i> , <i>Decapod hepanhamaparvovirus</i> 1 (1) <i>Penstylhamaparvovirus</i> , <i>Decapod penstylhamaparvovirus</i> 1 (1)	ssDNA, linear, 4 to 6 kb	Icosahedral T=1, 21 to 28 nm diameter	Decapods, diptera
<i>Permutotetraviridae</i> <i>Phasmaviridae</i> (<i>Bunyavirales</i>)	<i>Alphapermutotravivirus</i> , <i>Thosea asigna virus</i> (2) <i>Feravirus</i> , <i>Ferak feravirus</i> (1) <i>Jonvirus</i> , <i>Jonchet jonvirus</i> (1) <i>Orthophasmavirus</i> , <i>Kigluaik phantom orthophasmavirus</i> (9) <i>Sawastrivirus</i> , <i>Sancia sawastrivirus</i> (1) <i>Wuhivirus</i> , <i>Insect wehuvirus</i> (1)	+ ve ssRNA, monopartite, 5.7 kb – ve ssRNA, tripartite Fera-1.5, 4.2, 6.9 kb Jonvirus-1.7, 5.4, 6.9 kb Ortho-2.2, 2.8, 6.7 kb Sawastri -1.6, 4.2, 7.2 kb	Icosahedral T=4, 40 nm diameter Nucleocapsid pseudocircular ribonucleoprotein core, spherical, 80 nm diameter virus, enveloped. Jonchet virions can also appear rod shaped with a diameter of 60 nm by up to 600 nm in length	lepidoptera Mosquitoes, cockroach, midges, water striders, dragon flies, bees
<i>Phenuiviridae</i> (<i>Bunyavirales</i>)	<i>Goukovirus</i> , <i>Gouléako virus</i> (3) <i>Phasivirus</i> , <i>Badu phasivirus</i> (5) <i>Phlebovirus</i> , <i>Rift Valley fever phlebovirus</i> (60) <i>Wenrivirus</i> , <i>Shrimp wenrivirus</i> (1)	– ve ssRNA, tripartite Gouko-1.1, 3.2, 6.4 kb Phasi-1.3, 4.1, 6.8 kb Phlebo-1.7, 3.2, 6.4 kb	Virions typically spherical with diameters 80 to 130 nm with surface proteins arranged in a T=12 icosahedral lattice with three RNP coils in the core	Gouko, mosquitoes Phasi, mosquitoes and flies Phlebo, mosquito vector Wenri, shrimp Ants, midges
<i>Polycipiviridae</i> (<i>Picornavirales</i>)	<i>Chipolycivirus</i> , <i>Chironomus riparius virus</i> 1 (2) <i>Hupolycivirus</i> , <i>Hubei hupolycivirus</i> (1) <i>Sopolycivirus</i> , <i>Solenopsis invicta virus</i> 2 (11)	+ ve ssRNA, monopartite, 10 to 12 kb	Icosahedral, pseudo T=3, 33 nm diameter	Ants, midges
<i>Polydnaviridae</i>	<i>Bracovirus</i> , <i>Cotesia melanoscela bracovirus</i> (32) <i>Ichnovirus</i> , <i>Campoletis sonorensis ichnovirus</i> (21)	dsDNA, circular, multipartite Bracovirus, 15 to 30 segs, 2 to 31 kb each, 25 to 600 kb aggregate size Ichnovirus, 20 to 50 segs, 2 to 20 kb each, 150 to 250 kb aggregate size	Bracovirus, multiple rod shaped nucleocapsids, enveloped Ichnovirus, prolate ellipsoid, enveloped	Parasitoid hymenoptera

(Continued)

Table 1 Continued

Family/Subfamily Order	Genus, Subgenus, Type Species (total # in genus)	Genome type, segments and size	Morphology, T value for icosahedral capsids	Major invertebrate host
<i>Poxviridae</i> <i>Chordopoxvirinae</i> (<i>Chitovirales</i>)	<i>Centapoxvirus</i> , <i>Yokapox virus</i> (2)	dsDNA genome phylogenetically more <i>Orthopoxvirus</i> -like than any entomopoxvirus	Poxvirus like morphology	Mosquito but kills suckling mice and replicates in Vero cells
<i>Poxviridae</i> <i>Entomopoxvirinae</i> (<i>Chitovirales</i>)	<i>Alphaentomopoxvirus</i> , <i>Melolontha melolontha entomopoxvirus</i> (7) <i>Betaentomopoxvirus</i> , <i>Amsacta moorei entomopoxvirus</i> (16) <i>Deltaentomopoxvirus</i> , <i>Melanoplus sanguinipes entomopoxvirus</i> (1) <i>Gammaentomopoxvirus</i> , <i>Chironomus luridus entomopoxvirus</i> (2)	dsDNA, linear, 230 to 375 kb	Brick shaped 140 to 260 × 220 to 450 nm enveloped complex morphology	Mosquitoes, coleoptera, lepidoptera, orthoptera,
<i>Reoviridae</i> <i>Sedoreovirinae</i> (<i>Reovirales</i>)	<i>Cardoreovirus</i> , <i>Eriocheir sinensis reovirus</i> (1) <i>Phytoreovirus</i> , <i>Wound tumor virus</i> (3) <i>Seadornavirus</i> , <i>Banna virus</i> (3)	dsRNA all with 12 segments <i>Cardoreovirus</i> 0.7 to 3.7 kb <i>Seadornavirus</i> 0.9 to 3.7 kb <i>Phytoreovirus</i> 1.4 to 4 kb	Icosahedral, 2 shells, T=2 (inner shell) T=13 (intermediate shell), 60 to 70 nm diameter ¹	Cardio, crabs Phyto, leafhopper (and plants) Seadorna, mosquitoes (and mammals)
<i>Reoviridae</i> <i>Spinavirinae</i> (<i>Reovirales</i>)	<i>Aquareovirus</i> , <i>Aquareovirus A</i> (7) <i>Coltivirus</i> , <i>Colorado tick fever coltivirus</i> (5) <i>Cypovirus</i> , <i>Cypovirus 1</i> (16) <i>Dinovernavirus</i> , <i>Aedes pseudoscutellaris reovirus</i> (1) <i>Idnoreovirus</i> , <i>Idnoreovirus 1</i> (5)	dsRNA 9 to 12 segments Aqua-11 segs, 0.8 to 3.9 kb Colti-12 segs, 0.7 to 4.3 kb Cypo-10 segs, 1 to 4.2 kb Dinoverna-9 segs, 1.1 to 3.8 kb Idno, 10 segs, 1 to 4.8	Icosahedral single (T=2) or dual (T=2/T=13) shell Aqua-dual shell, 75 nm diameter Colti-dual shell, 60 to 80 nm diameter Cypo-single shell, 65 nm diameter Dinoverna-single shell T=2 only, 50 nm diameter Idno, dual shell T=2/T=13, 70 nm diameter	Aqua, crab and oyster Colti, ticks and mosquitoes Cypo, lepidoptera Dinoverna, <i>Aedes</i> mosquitoes Idno, hymenoptera
<i>Rhabdoviridae</i> (<i>Mononegavirales</i>)	<i>Almendravirus</i> , <i>Puerto Almendras alمندravirus</i> (6) <i>Alphanemrhavirus</i> , <i>Xingshan alphanemrhavirus</i> (2) <i>Caligrhavirus</i> , <i>Lepeophtheirus caligrhavirus</i> (3) <i>Sigmavirus</i> , <i>Drosophila melanogaster sigmavirus</i> (7)	– ve ssRNA, monopartite, 10.8 to 16.1 nm	Bullet shaped, helical rod shaped nucleocapsid 45 to 100 nm × 100 to 430 nm with matrix and envelope	mosquito, butterflies bed bugs, nematodes, sea lice, flies
<i>Roniviridae</i> (<i>Nidovirales</i>)	<i>Okavirus</i> , (Subgenus <i>Tipravirus</i>) <i>Gill-associated virus</i> (3)	+ ve ssRNA, monopartite, 26 kb	Bacilliform 40 to 60 nm × 150 to 200 nm, enveloped with peplomers	Crustaceans (prawns)
<i>Sarothroviridae</i>	<i>Macronovirus</i> , <i>Macrobrachium satellite virus 1</i> (1)	+ ve ssRNA, monopartite, 0.8 kb	Icosahedral T=? 15 nm diameter naked	Prawns, crayfish, butterflies, water bugs
<i>Solinviviridae</i> (<i>Picornavirales</i>)	<i>Invictavirus</i> , <i>Solenopsis invicta virus 3</i> (1) <i>Nyfulvavirus</i> , <i>Nylanderia fulva virus 1</i> (1)	+ ve ssRNA, monopartite, 8 to 11 kb 5' Vpg, 3' polyA	Icosahedral T=3 27 to 29 nm diameter	Ants
<i>Tospoviridae</i> (<i>Bunyavirales</i>)	<i>Orthotospovirus</i> , <i>Tomato spotted wilt orthotospovirus</i> (26)	– ve ssRNA, tripartite, 3, 4.8, 8.8 kb	Pseudocircular ribonucleoprotein core, 80 to 120 nm diameter, enveloped	Thrips
<i>Xinmoviridae</i> (<i>Mononegavirales</i>)	<i>Anphevirus</i> , <i>Xincheng anphevirus</i> (7)	– ve ssRNA, monopartite, 12 kb	Not seen, based solely on sequence	Mosquitoes, drosophila, orthoptera

^aThe taxon Order, if any is in brackets below the family or subfamily name. The taxon Subfamily, if any, is below Family name and is indented. The number of species in a genus is in brackets after the Genus name.

Note: Some families in this list also include viruses that infect more than invertebrates.

ICTV of any of these viruses can consult the ICTV Taxonomy Database for any virus species mentioned, at “See Relevant Websites section”. This site is updated on a regular basis following approval of new taxa by the ICTV. Any reference to taxa in the articles in this Volume are based on that posted as of Aug 31, 2020.

Below are provided brief synopses of the virus families, in alphabetical order, which include viruses which infect invertebrates. In addition to family names, names of additional taxa including Order, Subfamily, Genus and Species are also provided. The total number of species for each genus are included in brackets after the genus name and is based on the ICTV Taxonomy list as of August 31, 2020. Also provided are the years that the corresponding names for the taxa were first approved by the ICTV. Note that by the rules of orthography of the ICTV, the names of taxa (e.g., Order, ending in “*virales*”, Family, ending in “*viridae*”, Subfamily ending in “*virinae*”, genus, one word ending in “*virus*”, and Species, two or more words ending in “*virus*”) are in italics and names of viruses are in normal Roman letters. Also given are the names of exemplar viruses of each type species. It will be noticed that in most cases the species names are derived directly from the names of a virus classified into that species, the only difference being that the species name is in italics and the virus name is in normal font.

A fuller description of most of these are provided in the rest of the articles in Viruses of Invertebrates.

Artoviridae

Family: *Artoviridae* [ICTV 2018] (Order *Mononegavirales*, ICTV 1990)

Genus: *Hexartovirus* [ICTV 2019] (2 species)

Type Species: *Caligid hexartovirus* [ICTV 2019]

Species Exemplar: *Lepeophtheirus salmonis* negative-strand RNA virus-1

Genus: *Peropuvirus* [ICTV 2016] (6 species)

Type Species: *Pteromalus puparum peropuvirus* [ICTV 2016]

Species Exemplar: *Pteromalus puparum* negative strand RNA virus-1

Artoviruses, originally discovered by high throughput sequencing, belong to the order *Mononegavirales* and hence have a single negative sense (–ve) ssRNA genome which is up to 12.5 kb in length. The two genera in the *Artoviridae* family (*Arto* from arthropod), *Peropuvirus* (from *Pteromalus puparum* negative-strand RNA virus, PpNSRV-1) with six species and *Hexartovirus* (from the crustacean host crab, *Hexanauplia* and *artovirus*) with two species. PpNSRV-1 was initially reported in 2017 in a pteromalid wasp, *Pteromalus puparum*, hence the name of the virus. Other members of the *Peropuvirus* genus have been found in other parasitic wasps, pillworms, woodlice, odonates and copepods, while members of the *Hexartovirus* genus are associated with copepod sea lice or barnacles. PpNSRV-1 virions, the only artovirus virions to be described, are enveloped with a diameter of 100–130 nm. PpNSRV-1 is transmitted vertically through both male and female wasps and is present in various tissues throughout the life stages. While PpNSRV-1 increases adult longevity, infection does have a fitness cost. PpNSRV-1 particles are present in the follicular cells and ovaries of the parasitoid wasp host and in intracellular vesicles of the digestive tract. Virions for the other artoviruses have not been described as they have been identified solely from metagenomic studies. Collectively artovirus genomes encode nucleocapsid protein (N), glycoprotein (G) RNA directed RNA polymerase domain in the large (L) protein along with some proteins of unknown function, U1 to U3. Transcription initiation and termination motifs, typical of other mononegavirales viruses flank the independently transcribed ORFs.

Ascoviridae

Family: *Ascoviridae* [ICTV 1998] (Order *Pimascovirales*, ICTV 2019)

Genus: *Ascovirus* [ICTV 1998] (3 species)

Type Species: *Spodoptera frugiperda ascovirus 1a* [ICTV 1998]

Species Exemplar: *Spodoptera frugiperda* ascovirus 1a

Genus: *Toursvirus* [ICTV 2015] (1 species)

Type Species: *Diadromus pulchellus toursvirus* [ICTV 1998]

Species Exemplar: *Diadromus pulchellus* toursvirus 4a (DpTV)

Ascoviruses are unusual viruses of lepidopteran insects that appear to be horizontally transmitted by endoparasitoid wasps during oviposition and have a wide tissue tropism. They are bacilliform or allantoid shaped virions about 130–150 nm in diameter and 300–400 nm in length with an inner, enveloped, 80 × 300 nm core surrounded by a second, outer layer of protein subunits. Their large circular dsDNA genome is 100–200 kb in size encoding 117–180 genes. In addition to their highly complex structures, ascoviruses initiate an unusual cytopathology starting in the nucleus followed by enlargement of the infected cell and its eventual cleavage into 10–30 vesicles similar to apoptotic vesicles. Virion morphogenesis, including development of the inner core surrounded by de novo synthesized membrane and envelopment by an outer membrane is completed within the vesicles as the cell ruptures. As the virions accumulate near the periphery of the vesicles, they often form occlusion bodies in a “foamy” vesicular matrix. When these abundant, highly refractile vesicles accumulate in the hemolymph they form a milky white appearance. Ascoviruses share 9 core genes with iridoviruses and the giant marseilliviruses infecting amoeba. Phylogenetic analysis suggests that iridoviruses and ascoviruses share a common ancestor which is shared with marseilliviruses.

Baculoviridae

Family: *Baculoviridae* [ICTV 1975]

Genus: *Alphabaculovirus* [ICTV 2008] (55 species)

Type Species: *Autographa californica multiple nucleopolyhedrovirus* [ICTV 1979]

Species Exemplar: *Autographa californica multiple nucleopolyhedrovirus* (C6)

Genus: *Betabaculovirus* [ICTV 2008] (26 species)

Type Species: *Cydia pomonella granulovirus* [ICTV 1991]

Species Exemplar: *Cydia pomonella granulovirus* (Mexican 1)

Genus: *Deltabaculovirus* [ICTV 2008] (1 species)

Type Species: *Culex nigripalpus nucleopolyhedrovirus* [ICTV 2004]

Species Exemplar: *Culex nigripalpus nucleopolyhedrovirus* (Florida 1997)

Genus: *Gammabaculovirus* [ICTV 2008] (2 species)

Type Species: *Neodiprion lecontei nucleopolyhedrovirus* [ICTV 2002]

Species Exemplar: *Neodiprion lecontei nucleopolyhedrovirus*

Baculoviruses are among the most studied of any invertebrate virus. These viruses infect only insects, specifically lepidoptera (alpha and betabaculoviruses), diptera (gammabaculoviruses) and hymenoptera (*deltabaculoviruses*). Although baculovirus-like viruses in occlusion bodies have been described in shrimp, their taxonomic status has not been verified.

From a historical perspective, baculoviruses were initially recognized as agents which caused jaundice (or flacherie) disease of silkworm. The “polyhedrosis” which was associated with this disease was due to polyhedral bodies observed in liquified silkworm which died of the disease. In the late 1860s it was Louis Pasteur who raised the hypothesis that the “flecherie” disease of silkworm was due to a bacterium, later in the 1920s identified as a virus by Glaser and Paillot. The involvement of polyhedrosis diseases on reducing pest insect populations led to a lot of research interest in identifying and characterizing the causative agent and using them for biological control. Perhaps the first evidence of their potential for insect control was the unforeseen introduction of gHNPV, a nuclear polyhedrosis virus (NPV) through parasitoids from Finland, into a population of the European spruce sawfly, *Gilpinia hercyniae*, a serious pest of spruce in Canada in 1938. As reported by a mentor for the author of this article, Fred Bird of the Insect Pathology Research Institute in Sault Ste Marie, Ontario, Canada, by 1945 the sawfly infestation essentially collapsed and is still being kept in check by this virus. This was followed shortly by control of another sawfly pest, *Neodiprion sertifer* by introduction from Sweden of NeseNPV, now commercialized as Neocheck-s, by Gerry Wyatt of Watson and Crick fame. Gerry observed that in NPV DNA the ratio of A:T and of G:C were 1 irrespective of the NPV source, leading to the theory of the double stranded nature of the DNA double helix. As is often the case with fundamental research, the study of the molecular biology of baculoviruses, largely by the laboratories of Lois Miller (University of Georgia) and Max Summers (Texas A&M University) led to the development of the baculovirus expression system (BEVS) now in universal use for production of bioreagents and vaccines, including against COVID-19, and as gene delivery vectors.

Baculoviruses are characterized by two morphological forms, budded virus (BV) and occlusion-derived virus (ODV). Budded virus, as the name implies, are virions which have budded from infected cells to form rod-shaped virions with helical nucleocapsids measuring 30–60 nm in diameter by 250–300 nm in length surrounded by an envelope derived from the plasma membrane and containing the major envelope protein GP64 or F. The ODV has an almost identical nucleocapsid and is surrounded by an inner nuclear membrane-derived envelope and, as the name implies, is occluded in an occlusion body, made of either polyhedrin (nucleopolyhedroviruses) or granulin (granuloviruses, GVs). The circular dsDNA genome of a given baculovirus is identical between the budded and occlusion derived form and ranges in size from 82 (NeleGV) to 179 kb (XecnGV), encoding 81–183 ORFs. Unsurprisingly the baculovirus phylogeny, based on 38 core baculovirus genes, matches that of the taxonomy, with the *deltabaculovirus* and *gammabaculoviruses* being more ancient and the *alphabaculoviruses* being divided into two clades representing Groups I and II, respectively.

During infection, the polyhedra or granules disassemble in the alkaline insect gut, releasing the ODVs which pass through the peritrophic membrane of the gut lumen, aided by metalloprotease enhancers. Virion nucleocapsids enter the microvilli of midgut epithelial cells via membrane fusion, assisted by a complex of *per os* infectivity factors. In contrast to the ODVs, BVs infecting other cells of the host or tissue culture cells enter via receptor-mediated endocytosis. In both cases the nucleocapsids are released into the cytoplasm of the cells to initiate infection. Nucleocapsids are transported to the nuclei where they become uncoated and initiate a temporally regulated cascade of immediate early, delayed early, late and very late virus gene transcription. Following nuclear hypertrophy, viral DNA replication and viral protein synthesis, nucleocapsids begin to be formed within the nucleus.

Early in infection, nucleocapsids escape the ring zone in the nucleus and through actin-mediated transport, traverse the cytoplasm to the plasma membrane, via microtubules, collecting at so called budding sites where the major envelope protein GP64 (or F for some baculoviruses) has formed foci, in association of another viral protein ME53. GV envelopes do not contain a fusion protein suggesting that budded GVs might not play a role in vivo. As the nucleocapsids bud through the plasma membrane they are enveloped by the membrane and are released as BVs which spread through the hemocoel or trachea to other tissues, or cell to cell transmission in tissue cultures.

Late in infection, and in the same cells producing BVs, the nucleocapsids remain in the nucleus. They become enveloped by a membrane derived from the inner nuclear envelope which contains, among other viral proteins, the *per os* infectivity factors forming the occlusion-derived viruses. The ODVs are then assembled within polyhedra or granules based on the major occlusion body protein, polyhedrin (alpha, delta and gamma-baculoviruses) or granulin (betabaculovirus).

At the end of the infection the concerted activity of viral chitinase and cathepsin enzymes results in the liquefaction of the larvae and dissemination of the polyhedra or granules in the environment to infect other insects. Assisted in this dissemination is a curious baculovirus modification of behavior in which the infected larvae migrate to the tops of the plants they are on prior to death, a character called "Wipfelkrankheit".

As noted earlier, baculoviruses have also been developed as high-level protein expression systems, now widely commercialized and used for the development of bioactive reagents. This was a consequence of basic fundamental research completely unrelated to their use as biological control agents. At regular seminars held on Friday afternoons in the early 1980s at the Chicken Oil Company in College Station Texas, home of Texas A&M University, Gale Smith and others from the Max Summers lab noted that polyhedrin was the major protein produced in baculovirus-infected cells amounting to as much as 50% of the total protein. This led to a more in-depth characterization by Gale Smith, Max Summers and Malcolm Fraser, in 1983, of the polyhedrin promoter (in the absence of sequencing) showing that sequences upstream of the polyhedrin ORF did contain a powerful polyhedrin promoter and was capable of directing expression of human β interferon. This promoter was the basis of developing the baculovirus expression vector system (BEVS). This system has been expanded to utilize the p10 promoter, another highly expressed late promoter and others such as the orf46 promoter of SeMNPV.

This BEVS system led to the production of literally thousands of different proteins, some of pharmacological and diagnostic importance, such as specific antibodies, immunotherapeutic agents, virus-like particles and vaccines. Baculoviruses are also being considered as gene therapy vectors showing some early encouraging results. For example, baculoviruses expressing a Shigatoxin A subunit known to kill cancer cells, successfully reduced tumors in mice with MCF7-induced breast cancer after injection of the tumor. This author was not surprised to learn that BEVS was being used to generate diagnostic reagents and vaccines to address the 2019/2021 COVID-19 pandemic.

Bidnaviridae

Family: *Bidnaviridae* [ICTV 2011] (Order *Poliovirales*, ICTV 2008)

Genus: *Bidensovirus* [ICTV 2011] (1 species)

Type Species: *Bombyx mori bidensovirus* [ICTV 2011]

Species Exemplar: *Bombyx mori bidensovirus* 3 (VD1)

Bidensoviruses, which caused a denonucleosis in infected silkworm larvae were originally classified as parvoviruses because of their single stranded linear DNAs encapsidated separately into small icosahedral capsids. However bidensoviruses BmBDV-2 and BmBDV-3 are quite different from other densoviruses in that they have a bisegmented dsDNA genome that in aggregate (13 kb) is larger than the 4–6 kb of densoviruses, encodes a DNA polymerase, no densovirus ORFs, has a different transcription strategy and has no identity with densovirus genomes. Consequently, in 2012 they were re classified in the new family *Bidnaviridae*, genus *Bidensovirus*, type species *Bombyx mori bidensovirus*.

Bidensoviruses are naked, 20–24 nm diameter icosahedral viruses with a bisegmented linear ssDNA genome (6.5 kb VD1 and 6 kb VD2) with ITRs in which complementary strands are separately encapsidated into 4 virion types. Both strands of both segments generate transcripts expressing different proteins and hence the genome has an ambisense organization. To date, bidensoviruses have been isolated only from silkworm and hence the three isolates (Yamanashi, Zhenjiang and Indian) are referred to as BmBDVs. In terms of evolution, bidensoviruses are quite unusual since different parts of the genome appear to originate from different sources. Based on bioinformatic analysis the BmBDV NS1 and VP may have been derived from parvoviruses, the DNAPolB might have evolved from the hypothetical ancestral polintoviruses, P133 may have come from an insect reovirus and NS3 from granuloviruses.

One strand of ambisense VD1 encodes transcripts for nonstructural proteins NS2 and NS1 and structural protein VP while the other strand encodes transcripts for protein-primed PolB. Though ORFs for NS2 and NS1 overlap, two different transcripts, with alternative initiation sites, are made. Leaky scanning of the VP ORF results in two VPs. One strand of ambisense VD2 encodes transcripts for the nonstructural NS3 and the other strand encodes the structural protein P133.

NS1 has DNA binding, ATPase and helicase activities suggesting it is a multifunctional protein important in virus replication. The function of NS2 is still unknown, though it shares slight sequence similarity with dnaA, a chromosomal replication initiator protein, and a DNA-binding response regulator. A homolog of NS3 in a densovirus is important for viral DNA replication. The VPs are the major structural proteins which can self-assemble if expressed in a baculovirus expression system, while P133 is a minor structural protein. Interestingly P133 has a homolog with the outer capsid protein of cypoviruses, members of the *Reoviridae* family. PolB is a protein-primed DNA polymerase that appears to be processed by post translational cleavage into three peptides with sizes of 53 (detected in purified virions), 70 and 120 kDa.

Infection of silkworm intestinal epithelial cells appears to be by receptor-mediated endocytosis through attachment of the virion VPs with a NSD-2, an amino transporter protein cell receptor protein. During infection there is nuclear hypertrophy with the appearance, late in infection, of a dense homogenous structure in the nuclei and concomitantly vacuolization of mitochondria and endoplasmic reticulum and formation of a large autophagosome. The dead columnar epithelial cells are sloughed out, along with the released viruses into bead-like frass. The mode of replication of BmBDV DNA is unknown though absence of replicative intermediates typical of parvovirus DNA replication seem to discount rolling circle replication. Rather, the protein-primed nature of the BmBDV DNAPolB and the presence of ITRs at the genome ends which could form a panhandle, suggest replication of BmBDV DNA might occur by protein priming, as is well described for replication of adenovirus DNA.

Infection of early instars results in the lengthening of times between instars while infection of late instars can result in pupation and adult emergence, but the weight and survival of pupae is compromised.

Birnaviruses of Invertebrates (*Entomobirnavirus*)

Family: *Birnaviridae* [ICTV 1984]

Genus: *Entomobirnavirus* [ICTV 1993] (2 species)

Type Species: *Drosophila X virus* [ICTV 1991]

Species Exemplar: *Drosophila X virus*

Viruses belonging to three genera of the family *Birnaviridae* infect non mammalian vertebrates. The fourth genus represents entomobirnaviruses infecting exclusively insects and are classified in the genus *Entomobirnavirus*. Originally discovered as a contaminant in a fruit fly cell culture, at least four other birnaviruses have also been found in free-living mosquitoes and drosophila. One birnavirus recovered in a mosquito cell line, Espirito Santo virus, was found in a sample from a Dengue-3 virus-infected patient from Brazil.

Like other birnaviruses, they have an icosahedral $T = 3$ symmetry and a dsRNA genome which, as the name implies, is bisegmented. One segment is about 3.2 kb and the other about 3.4 kb in length, with VPg, a virion protein derived from VP1 and linked to the RNA genome, covalently attached at the 5' end of the positive sense strand of each ds genomic RNA. The 3.4 kb segment A encodes a 114 kDa polyprotein precursor which is proteolytically cleaved by the VP4 protease into structural capsid proteins in the order on the polyprotein, preVP2, VP4 and VP3. A fourth VP, VP5 is encoded in frame with VP4. In addition to being a capsid protein, VP3 has anti RNAi activity suppressing antiviral RNAi. The 3.2 kb segment B encodes the RdRp. Little is known of the entomobirnavirus replication cycle, but it is likely that genome replication and transcription are similar to that of other birnaviruses, covered elsewhere in the encyclopedia. Entomobirnaviruses cause a cytopathic effect in infected insect cells including cell aggregation and ending in death. *Drosophila X virus* can result in a persistent infection often resulting in oxygen starvation causing death.

Dicistroviridae

Family: *Dicistroviridae* [ICTV 2002] (Order *Picornavirales*, ICTV 2008)

Genus: *Aparavirus* [ICTV 2009] (6 species)

Type Species: *Acute bee paralysis virus* [ICTV 2004]

Species Exemplar: *Acute bee paralysis virus*

Genus: *Cripavirus* [ICTV 2002] (4 species)

Type Species: [ICTV 1982] *Cricket paralysis virus*

Species Exemplar: *Cricket paralysis virus*

Genus: *Triatovirus* [ICTV 2015] (5 species)

Type Species: [ICTV 2002] *Triatomavirus*

Species Exemplar: *Triatoma virus*

Dicistroviruses are a group of highly stable +ve sense ssRNA viruses which, unlike other picornavirales viruses, has a bicistronic genome encoding two ORFs separated by an intergenic ribosome entry site (IRES), a characteristic which led to their name as dicistroviruses. They are 30 nm diameter icosahedral viruses with a pseudo $T = 3$ symmetry and composed of 4 viral proteins, VP1, 2, 3 and 4. As a group dicistroviruses have a broad host range including many insects like bees, ants, crickets, aphids, drosophilids, lepidoptera and triatomes, the vector of Chagas disease, and other arthropods such as shrimp and crabs. Thus, they are of great economic and medical importance and some dicistroviruses have been touted as biological control agents for them.

The 8.5–20 kb +ve sense ssRNA genome has a VPg covalently linked to the 5' end containing two ORFs, ORF1 and ORF2. ORF1 is preceded by a 5' IRES which, along with the intergenic IRES between the two ORFs and a 3' polyA tail, allows for translation of both ORFs in a cap-independent manner. ORF1 encodes nonstructural proteins including a helicase, the VPg, protease and RNA dependent RNA polymerase (RdRp). ORF2 encodes the four structural proteins VP1, 2, 3 and 4. While the receptor for attachment to cells is still unknown, dicistroviruses enter cells via clathrin-mediated endocytosis. The rest of the replication cycle is similar to the picornaviruses, including the synthesis of the ORF1 and ORF2 polyproteins which are auto proteolytically cleaved into the smaller functional proteins. The VPg is uridylylated at a tyrosine residue by the viral RdRp allowing it to serve as a primer for replication of both the -ve and +ve sense strands.

Most of the dicistroviruses infect mostly the gut and shed virus into the gut lumen, eliminating it through the feces which enables efficient transmission of the virus. However, dicistroviruses infecting hymenoptera infect all developmental stages and replicate in most tissues. Infection is associated with nutritional stress and in bees can be manifest in neurological signs such as paralysis, trembling and flightlessness and ultimately death. Infections due to dicistroviruses have been associated, along with other factors, with the worldwide colony collapse disorder of beehives in 2006–2007 and continues to plague the honey industry. Dicistroviruses also cause losses in the crab and shrimp industries, being the causative agents of sleeping disease by Mud crab virus and Taura syndrome in penaeid shrimp due to Taura syndrome virus. Many dicistroviruses are transmitted horizontally through the fecal-oral route, while in hymenoptera, virus transmission can be food-borne, venereal, vector borne and vertical.

Hytrosaviridae

Family: *Hytrosaviridae* [ICTV 2011]

Genus: *Glossinavirus* [ICTV 2011] (1 species)

Type Species: *Glossina hytrosavirus* [ICTV 2011]

Species Exemplar: *Glossina pallidipes* salivary gland hypertrophy virus (Uganda)

Genus: *Muscavirus* [ICTV 2011] (1 species)

Type Species: *Musca hytrosavirus* [ICTV 2011]

Species Exemplar: *Musca domestica* salivary gland hypertrophy virus

Hytrosaviruses are large dsDNA viruses of diptera, mostly tsetse fly and houseflies and syrphid fly. Though the symptoms of salivary gland hypertrophy in tsetse flies were first described in the 1930s, the etiological viral agent exhibiting as virus-like rods, was not described until 1978. In hytrosavirus-infected insects the salivary glands swell to up to four times normal size, leading to the origin of the name salivary gland hypertrophy virus. They are now classified in the family *Hytrosaviridae* which has two genera, *Glossinavirus* and *Muscavirus*, named after the host of the virus in the genus. Each genus has a single species which is the type species, *Glossina hytrosavirus* in genus *Glossinavirus* and *Musca hytrosavirus* in genus *Muscavirus*. Though not always lethal, infection is associated with reproductive dysfunctions including infertility and distorted mating behaviors. The *Musca hytrosavirus* *Glossina pallidipes* salivary gland hypertrophy virus is particularly problematic in raising tsetse flies, the causative agent of African sleeping sickness, for the very effective sterile male release program using the sterile insect technique (SIT). Once in a colony, the hytrosavirus results in collapse of the colonies as happened in the Seibersdorf, Austria tsetse fly culture.

Virions are rod-shaped with a diameter of 50–65 nm and length of 500–1000 nm with a bilipid membrane envelope and circular dsDNA genomes 124–190 kb in length. They are not only structurally similar to other large dsDNA invertebrate viruses like baculoviruses, nudiviruses and nimaviruses but they share about 12 of the 38 core genes common to them. Little is known of their replication cycle. They appear to be infected through the tracheal system. Viral capsids are released into the cytoplasm through membrane fusion. Through the cell's microtubule system, the capsids move to the nucleus to initiate transcription of immediate early, early and late genes. More detailed studies of these early stages are hampered by lack of a more tractable cell culture system. Nucleocapsids can be observed leaving the nucleus through nuclear pores and exiting the cell by budding through the membrane of cells bordering the salivary gland lumen.

Transmission of *Glossina hytrosavirus* in tsetse flies is both horizontal, due to feeding of contaminated blood and vertical through trans-ovum transmission or through infected milk. Transmission of *Musca hytrosavirus* is largely horizontal through gregarious feeding of the houseflies.

Iflaviridae

Family: *Iflaviridae* [ICTV 2011] (Order: *Picornavirales*, ICTV 2008)

Genus: *Iflavirus* [ICTV 2008] (15 species)

Type Species: *Infectious flacherie virus* [ICTV 2002]

Species Exemplar: *Infectious flacherie virus*

Iflaviruses are small icosahedral viruses 22–30 nm in diameter with a monopartite 8–10.5 kb + ve ssRNA genome with a VPg at the 5' end and a templated polyA tail at the 3' end. They infect only arthropods, namely insects including honeybees, lepidoptera, aphids and planthoppers and arcnids, such as mites parasitic on honeybees. Genus, *Iflavirus* numbering 15 species to date includes the type species *Infectious flacherie virus* represented by a silkworm virus, *Infectious flacherie virus* from which the genus and species names are derived. Their cellular replication cycle is thought to be similar to that of other picornaviruses in the *Picornavirales* including cap-independent translation due to an IRES 5' to the polyprotein ORF and involving auto catalytic cleavage into structural proteins and the RdRp.

Iflaviruses are transmitted largely through contaminated food and often result in a permissive infection sometimes resulting in vertical transmission. Some symptomatic infections do occur resulting in diarrhea, developmental abnormalities and death of the host. Iflavirus infections of honeybees have been linked, along with other bee viruses, with colony collapse disorders and as such they are of economic importance.

Iridoviruses of Invertebrates (*Betairidovirinae*)

Family: *Iridoviridae* [ICTV 1975] (Order: *Pimascovirales*, ICTV 2019)

Subfamily: *Betairidovirinae* [ICTV 2016]

Genus: *Chloriridovirus* [ICTV 1981] (5 species)

Type Species: *Invertebrate iridescent virus 3* [ICTV 1999]

Species Exemplar: Mosquito iridescent virus

Genus: *Decapodiridovirus* [ICTV 2018] (1 species)

Type Species: [ICTV 2018] *Decapod iridescent virus 1*

Species Exemplar: Shrimp hemocyte iridescent virus

Genus: *Iridovirus* [ICTV 1971] (2 species)

Type Species: *Invertebrate Iridovirus 6* [ICTV 1999]

Species Exemplar: Chilo iridescent virus

The *Irodoviridae* family represents large icosahedral viruses classified into two subfamilies. Viruses in the subfamily *Alphairidovirinae* infect ectothermic vertebrates including bony fishes, amphibians and reptiles. The second subfamily, *Betairidovirinae*, includes all iridescent viruses of invertebrates. It has three genera, *Chloriridovirus* with five species, *Decapodiridovirus* with one species and the original genus *Iridovirus*, with two species. The invertebrate iridescent viruses are among the largest icosahedral viruses with diameters up to 200 nm and symmetries of $T = 147$ to 217. Though they have an icosahedral structure, they can be more complex including having an internal membrane enveloping the nucleoprotein core containing a linear dsDNA genome of 163–220 kb that is circularly permuted with terminal redundancies. While some are naked, iridoviruses that bud from infected cells will have an additional membrane surrounding it. They have a fairly broad host range infecting 6 orders of insects including mosquitoes and lepidoptera and crustaceans, like isopods, molluscs and oysters (*Decapodiridoviruses*) and even some vertebrates. For example, iridolike viruses cause gill necrosis and oyster velar virus disease in oysters. The viruses are highly stable in water but thermolabile and sensitive to dry conditions. Viruses enter susceptible cells via clathrin-mediated endocytosis, in the case of IIV-6 using ORF 096 L as the virus attachment molecule. Transcription is temporally regulated into immediate early and delayed early phases and a viral RNA polymerase II-mediated late phase. Genome size or slightly longer DNA molecules are first generated in the nucleus and after transport to the cytoplasm form concatemeric DNA facilitated by their terminal redundancy and are methylated. The concatemeric viral DNA is packaged by a “headful” process in which slightly longer than genome length DNA is packaged into virions as circularly permuted terminally redundant molecules. Virions are released from infected cells by cell lysis or by budding from the host cell membrane. Like many DNA viruses, iridoviruses code for anti-apoptotic proteins, like IIV-6 ORF193R, that are expressed early to protect the virus from the cells’ apoptotic machinery. However, late in infection they also induce apoptosis, mediated by viral proteins like the Chilo iridescent virus 389 L protein (iridoptin) which aids in viral dissemination to adjacent cells. Transmission between insects can be perorally or by endoparasitic hymenoptera. Infection can be patent, with an accumulation of high numbers of virions, giving rise to a visible iridescence, from which the viruses originally got their name. Infection is normally lethal or covert resulting in only a low level of virus particles, but still resulting in reduced fitness.

Malacoherpesviridae

Family: *Malacoherpesviridae* [ICTV 2008] (Order: *Herpesvirales*, ICTV 2008)

Genus *Aurivirus* [ICTV 2012] (1 species)

Type Species: *Haliotid herpesvirus 1* [ICTV 2012]

Species Exemplar: *Haliotid herpesvirus 1*

Genus *Ostreavirus* [ICTV 2008] (1 species)

Type Species: *Ostreid herpesvirus 1* [ICTV 2008]

Species Exemplar: *Ostreid herpesvirus 1*

The malacoherpesviruses are herpesviruses that infect a variety of marine invertebrates notably molluscs, like oysters (superfamily *Ostreioidea*) and abalones (sea snails in the family *Halitodidae*) and have a global economic impact, particularly in hatcheries. The oyster herpesvirus, OsHV-1, was the first malacoherpesvirus discovered and that was in adult Eastern oysters, *Crassostrea virginica* in 1972. It was also found to be responsible for mass mortality in Pacific oyster (*C. gigas*), European flat oyster (*Ostrea edulis*) and other oyster species. Disease outbreaks due to a second malacoherpesvirus, *Haliotis herpesvirus* HaHV-1, were also discovered in a variety of abalone species such as *Haliotis diversicolor supertexta*, *H. laevigata* and *H. rubra* and others beginning in 2005. The malacoherpesviruses have a typical herpesvirus morphology consisting of a 70–80 nm diameter icosahedral capsid with $T = 16$, surrounded by a trilaminar unit membrane giving an overall diameter of about 100–180 nm. However, the malacoherpesviruses lack the tegument usually associated with herpesviruses but instead have a 5 nm translucent gap between the capsid and outer viral membrane filled with fine fibrils. The linear dsDNA genomes of only two malacoherpesviruses have been sequenced including the ostreavirus OsHV-1 genome with 207,339 bp (NC_005881) and the aurivirus, abalone herpesvirus Victoria/AUS/2009 genome with a size of 211,518 bp (NC_018874). Both genomes are structured as in other herpesviruses, in the order $TR_L-U_L-IR_L-X-IR_S-U_S-TR_S$. For example, for OsHV-1, the genome is organized into a 3,370 bp unique short U_S and a 167,843 bp unique long U_L regions having two orientations each flanked by inverted repeats. U_L is flanked by 7,584 bp TR_L and IR_L and U_S is flanked by 9,774 bp TR_S and IR_S . However, the malacoherpesviruses differ from amniote herpesviruses in the family *Herpesviridae* and herpesviruses of fishes and amphibians in the family *Alloherpesviridae* by infecting only invertebrate hosts and their genomes are phylogenetically distinct from them. Consequently, during the re-examination of the order *Herpesvirales* they were classified in 2008 in a new family *Malacoherpesviridae* with two genera *Ostreavirus* for the oyster herpesviruses and *Aurivirus* for the abalone herpesviruses. The prefix “malaco” for this family name is derived from the word malaco, meaning soft, a term used to denote molluscs.

Mesoniviridae

Family: *Mesoniviridae* [ICTV 2012] (Order: *Nidovirales*, ICTV 1996)

Subfamily: *Hexponivirinae* [ICTV 2018]

Genus: *Alphamesonivirus* [ICTV 2002] (9 species)

Subgenus: *Namcalivirus* [ICTV 2018]

Type Species: [ICTV 2012] *Alphamesonivirus 1*

Species Exemplar: Cavally virus

Mesoniviruses are 50–120 nm diameter enveloped mosquito viruses with a monopartite 20 kb +ve sense ssRNA genome with a 5' cap and 3' polyA tail. For such a small group of very similar viruses in terms of morphology and a relatively tight nucleic acid phylogeny, mesoniviruses have a complicated taxonomy with a suborder *Mesonidovirineae* of the order *Nidovirales*, subfamily *Hexponivirinae*, family *Mesoniviridae*, one genus, *Alphamesonivirus* with a type species *Alphamesonivirus 1*. The genus is further subdivided into eight subgenera. The subgenera *Karsalivirus* and *Namcalivirus* each have two species, while each of the other six subgenera have only one species in the subgenus.

The genome consists of seven ORFs. The replicative enzymes ORF1a and 1b overlap and are translated by a ribosomal frame shift, facilitated by overlapping GGAUUUU sequences. ORF3a and 3b might similarly be translated by a ribosomal frame shift. ORF1a encodes a viral protease for autocatalytic processing of pp1a and pp1ab into smaller proteins. ORF1a and ORF1b encodes a polyprotein processed by autocatalytic cleavage to RdRp, helicase, exoribonuclease and two methyl transferases. The ORFs downstream of ORF1b, are for structural proteins, two Spike protein subunits, S1 and S2, the nucleocapsid protein N and 4 membrane spanning proteins (M). These are translated from two subgenomic RNAs, the synthesis of which are regulated by transcription regulating sequences (TRSs). The envelope consists of protruding spike-like projections and an integral membrane protein anchoring it to the nucleoprotein core.

To date mesoniviruses have been identified in only mosquitoes and one report of a mesonivirus from aphids based on next generation sequencing. While they replicate in some insect cells, they could not replicate in several mammalian and avian cell lines studied. Infection results in a variety of cytopathic effects, associated with a high and rapid yield of progeny viruses. Some mesoniviruses are maintained in the population by vertical transmission with transmission from female mosquitoes to her progeny, including male offspring. Horizontal transmission may occur via contaminated legs, wings and even saliva from naturally infected mosquitoes.

Nimaviridae

Family: *Nimaviridae* [ICTV 2002]

Genus: *Whispovirus* [ICTV 2002] (1 species)

Type Species: *White spot syndrome virus* [2008]

Species Exemplar: White spot syndrome virus-CN

White spot syndrome virus is the only species in the *Nimaviridae* family. Variants of White spot syndrome virus (WSSV), the only virus in the species, causes a highly contagious disease, White spot disease (WSD), after which the virus was named. The first WSD outbreak was in China and Taiwan around 1992 and spread to other shrimp farming countries like Japan, Thailand, the Americas, France and the Middle East. The virus has a broad host range among crustaceans, including shrimp, crayfish, crab and even lobster resulting in large economic losses in the related industries. Originally, because of the baculovirus-like rod shape of the nucleocapsid and its large ds circular DNA genome, their earlier names included Chinese baculo-like virus, *Penaeus monodon* baculovirus and white spot baculovirus. The names were changed to WSSV followed by letters designating their geographic origins and were first classified as species *White spot syndrome virus 1* in the family *Baculoviridae*. However due to significant differences in morphology and phylogeny between these viruses and baculoviruses, they were reassigned to a new family *Nimaviridae* (named for the threadlike tail, “nima” in Latin, of the virions) with a single genus, *Whispovirus*. The genus *Whispovirus* derives its name from the sole *White spot syndrome virus* species with the White spot syndrome virus-CN (WSSV-CN) as the exemplar isolate. This species is represented by 15 other isolates whose genomes have been completely sequenced including WSSVs from China, Japan, Taiwan, Thailand, Mexico, Australia, India, Brazil and Ecuador.

WSSVs are large, 70–170 in diameter by 210–320 nm in length, enveloped virions with a thread-like extension with an intermediate tegument layer containing a 65 × 300 nm rod-shaped nucleocapsid, reminiscent of baculovirus nucleocapsids. In addition to about 50 structural proteins, the virus also has lipid components. The large circular dsDNA genome is 281–309 kb in size and has nine internal homologous repeats similar to the *hrs* of baculovirus genomes. Only about 150 of the predicted 530 ORFs are thought to be functional. The WSSV genome also encodes some microRNAs targeting both viral and host genes. While there is some genotypic variability among the isolates, all are considered to be from the same species.

WSSV enters cells by caveola or clathrin-mediated endocytosis and alters host metabolism. Replication is nuclear with temporally regulated transcription divided into immediate early, early, late and very late phases. While most mRNAs have 3' polyA tails and 5'-caps there is no evidence of splicing, but some have IRESs which could be used to regulate translation. Like baculoviruses, the early genes have host-like RNAPolIII promoters, while late genes have a late gene promoter. Replication takes place entirely in the nucleus, including *de novo* formation of intranuclear viral envelope and morphogenesis of nucleocapsids.

The virus appears to target stomach, gills, lymphoid organs and connective tissue but not hepatopancreas and midgut, both of endodermal origin. Signs of infection include lethargy, a reddish coloration of the body and white spots, from which it derives its name.

Nodaviridae

Family: *Nodaviridae* [ICTV 1981] (Order *Nodamuvirales*, ICTV 2019)

Genus: *Alphanodavirus* [ICTV 1997] (5 species)

Type Species: *Nodamura virus* [ICTV 1981]

Species Exemplar: Black beetle virus

Alphanodaviruses replicate exclusively in insects, notably wax moth larvae, grass grubs, tsetse fly, reduviid bugs and mosquitoes. Viruses from genus *Betanodavirus*, the second of two genera in the family, infect fish. In 1975, the black beetle virus was the first

nodavirus discovered which was from black beetles (*Heteromychus arator*) in New Zealand. The virions are icosahedral with $T = 3$ symmetry and diameters of 32–33 nm and consisting of a single capsid protein (CP) or its two cleavage products. The Flock house virus CP is 44 kDa and the two cleavage products β and γ are 39 and 4 kDa in size, respectively. The +ve ssRNA genome is bisegmented with sizes of 1.3 and 1.4 kb. Following entry to the cytoplasm, three mRNAs, RNA1, which codes for the catalytic subunit of RdRp, RNA2 which codes for CP, and RNA3, which codes for B1 and B2 which function as suppressors of RNAi, are produced. Infection of hosts usually results in stunting, paralysis and death. Complete genome sequences have been deposited for black beetle virus, Boolarra virus, five Flock House viruses, two Nodamura viruses and one Pariacoto virus.

Nudiviridae

Family: *Nudiviridae* [ICTV 2013]

Genus: *Alphanudivirus* [ICTV 2013] (2 species)

Type Species: *Oryctes rhinoceros nudivirus* [ICTV 2013]

Species Exemplar: *Oryctes rhinoceros nudivirus* (Ma07)

Genus: *Betanudivirus* [ICTV 2013] (1 species)

Type Species: *Heliothis zea nudivirus* [ICTV 2013]

Species Exemplar: *Heliothis zea nudivirus* (1)

The first nudivirus recognized as a virus is probably the “non occluded baculovirus” that infected the Rhinoceros beetle in Samoa and which was used in 1967 as an effective biological control agent against this beetle. Since then it has had a convoluted taxonomic history, originally classified as a baculovirus, except that it did not form occlusion bodies like other baculoviruses. Through phylogenetic analysis, the nudiviruses are now classified in their own family, *Nudiviridae* organized into two genera, *Alphanudivirus* with two species including *Oryctes rhinoceros nudivirus* as the type species and *Betanudivirus* with *Heliothis zea nudivirus* as the sole member and type species. Nudivirus virions have a rod-shaped nucleocapsid and a circular dsDNA 96–232 kb genome, much like that of baculovirus genomes and are enveloped. The alphanudiviruses are more rounded in shape measuring 100×200 nm, while the betanudiviruses are more rod-shaped measuring 80×300 – 400 nm. They differed initially from baculoviruses in that they were non occluded, or naked, resulting in their current taxonomic designation as “nudi” viruses. However, some nudiviruses have enveloped or non enveloped occlusion bodies, which in some cases are facultative. They infect many orders of insects and are a major problem for the shrimp industry. Not much is known about their replication cycle.

OrNV attaches to cells and is taken in by pinocytosis. It is released into the cytoplasm upon fusion with lysosomal membranes and degeneration of the lysosomes. Presumably the nucleocapsids are transported to the nucleus where the DNA is released, initiating replication around 7 h post infection. Transcription is temporally regulated into early, intermediate and late stages with at least 100 transcripts being expressed. Viral envelopes and nucleocapsids and episomally replicated viral DNA assemble in the nucleus to be released into the cytoplasm followed by budding through the plasma membrane.

Heliothis zea nudivirus 1 (HzNV-1) was originally found in a persistently infected cell line IMC Hz-1. HzNV-1 causes gonadal atrophy in adult *Galleria mellonella*. In cells, HzNV-1 has both a productive (lytic) infection resulting in a high titer of virus and cell death and in some cells a persistent (latent) infection. Persistently infected cells can be passaged without cell lysis and viral DNA can be detected in episomal or integrated form. Two viral genes appear to be correlated with the switch between productive and latent infections. When a high concentration of HzNV-1 viral *hh1* is expressed in latently infected cells a lytic infection ensues. However if *pag1* encoded miRNAs targeting *hh1* are produced then a latent infection occurs.

As mentioned, nudiviruses have a broad host range in insects and shrimp. Transmission is through a *peroral* feeding of feces from virus-infected midgut epithelia and *per parenteral* mating routes. Consequences of infection can include reduced size, crippling, reduced fecundity, host sterility and death by fat body disintegration of infected individuals.

Nyamiviridae

Family: *Nyamiviridae* [2013] (Order *Mononegavirales*, ICTV 1990)

Genus: *Berhavirus* [ICTV 2018] (3 species)

Type Species: *Sipunculid berhavirus* [ICTV 2018]

Species Exemplar: Běihǎi rhabdo-like virus 4

Genus: *Crustavirus* [ICTV 2015] (3 species)

Type Species: *Wenzhou crustavirus* [ICTV 2015]

Species Exemplar: Běihǎi rhabdo-like virus 6

Genus: *Nyavirus* [ICTV 2013] (3 species)

Type Species: *Nyamanini nyavirus* [ICTV 2013]

Species Exemplar: Sierra Nevada virus

Genus: *Orinovirus* [ICTV 2018] (1 species)

Type Species: *Orinoco orinovirus* [ICTV 2018]

Species Exemplar: Orinico virus

Genus: *Socyvirus* [ICTV 2015] (1 species)

Type Species: *Soybean cyst nematode socyvirus* [ICTV 2013]

Species Exemplar: Soybean cyst nematode virus 1
 Genus: *Tapwovirus* [ICTV 2018] (1 species)
 Type Species: *Tapeworm tapwovirus* [ICTV 2018]
 Species Exemplar: Wēnzhōu tapeworm virus 1

Nyamiviruses, being in the Order *Mononegavirales*, have a non-segmented -ve ssRNA genome ranging from 8 to 12 kb in size, with the exception of *Tapwovirus* which has a bi-segmented – ve ssRNA genome with an aggregate size of 10.5 kb. The family *Nymaviridae* consists of six genera and a total of 12 species. The family is named for the *Nyavirus* genus (derived from *Nyamanini* Pan in South Africa from where the first *Nyavirus*, *Nyamanini virus*, was isolated). Viruses in that genus are tick-borne and can also infect birds. Many viruses in this family have been implied to exist only through next generation sequencing, so little virological and biological information, except their association with a broad range of invertebrates is available. Viruses in the genus *Berhavirus* are associated with marine echinoderms and sipunculids, those of genus *Crustavirus*, as the name implies, are associated with crustaceans, those of *Orinovirus* with moths, those of *Socyrivirus* with plant parasitic nematodes and those from *Tapwovirus* are from tapeworms. The *Nyamanini virus* virions are enveloped and spherical in shape with diameters of 100–130 nm and consisting of 5–6 structural proteins including the nucleocapsid protein (N), glycoprotein (G) and RdRP (L) based on sequence similarity to other mononegavirales sequences. The genomes of the different nyamiviruses encode 5–6 ORFs encoding structural proteins including N, G, P, L and some of unknown function. *Nyamanini virus* replicates in the nucleus but other aspects of virus replication is unknown, a major limitation of identifying viruses solely through metagenomics.

Parvoviruses of Insects (*Densovirinae* and *Hamaparvovirinae*)

Note: The family taxonomy of the *Parvoviridae* underwent a major reorganization as this article was being written. Below is the updated taxonomy as of August 2020.

Family: *Parvoviridae* [1975] (Order *Picovirales*, ICTV 2019)

Subfamily: *Densovirinae* [ICTV 1993]

Genus: *Aquambidensovirus* [ICTV 2019] (2 species)
 Type Species: *Decapod aquambidensovirus 1* (2) [ICTV 2019]
 Species Exemplar: *Cherax quadricarinatus densovirus*
 Genus: *Blattambidensovirus*, (1) [ICTV 2019] (1 species)
 Type Species: *Blattella blattambidensovirus 1* [ICTV 2019]
 Species Exemplar: *Blattella germanica densovirus*
 Genus: *Hemiambidensovirus* [ICTV 2019] (2 species)
 Type Species: *Hemipteran hemiambidensovirus 1* (2) [ICTV 2019]
 Species Exemplar: *Dysaphis plantaginea densovirus*
 Genus: *Iteradensovirus* [ICTV 2013] (5 species)
 Type Species: *Lepidopteran iteradensovirus 1* (5) [ICTV 2013]
 Species Exemplar: *Bombyx mori densovirus 1*
 Genus: *Miniambidensovirus* [ICTV 2019] (1 species)
 Type Species: *Orthopteran miniambidensovirus 1* (1) [ICTV 2019]
 Species Exemplar: *Acheta domestica miniambidensovirus*
 Genus: *Pefuambidensovirus* [ICTV 2019] (1 species)
 Type Species: *Blattodean pefuambidensovirus 1* (1) [ICTV 2019]
 Species Exemplar: *Periplanata fuliginosa densovirus*
 Genus: *Protoambidensovirus* [ICTV 2019] (2 species)
 Type Species: *Lepidopteran protoambidensovirus 1* (2) [ICTV 2019]
 Species Exemplar: *Galleria mellonella densovirus*
 Genus: *Scindambidensovirus* [ICTV 2019] (3 species)
 Type Species: *Orthopteran scinambidensovirus 1* (3) [ICTV 2019]
 Species Exemplar: *Acheta demostica densovirus*

Subfamily: *Hamaparvovirinae*

Genus: *Brevihamadensovirus* [ICTV 2019] (2 species)
 Type Species: *Dipteran brevihamadensovirus 1* (2) [ICTV 2019]
 Species Exemplar: *Aedes albopictus C6/36 cell densovirus*
 Genus: *Hepanhamaparvosovirus* [ICTV 2019] (1 species)
 Type Species: *Decapod hepanhamaparvosovirus 1* (1) [ICTV 2019]
 Species Exemplar: *Panemus merguensis hepandensovirus*
 Genus: *Penstylhamaparvovirus* [ICTV 2019] (1 species)
 Type Species: *Decapod penstylhamaparvovirus 1* (1) [ICTV 2019]
 Species Exemplar: *Decapod penstyldensovirus 1*

Viruses in the family *Parvoviridae* are small, naked icosahedral viruses with a small, linear, single stranded DNA genome about 4–6 kb in length. Parvoviruses are classified into three subfamilies based largely on the nature of their host. Those in the *Parvovirinae* subfamily infect vertebrates while those in the two subfamilies *Densovirinae* and *Hamaparvovirinae* infect invertebrate hosts. *Densovirinae* have eight genera including the original *Itaradensovirus*, and what used to be genus *Ambidensovirus*, which due to recent phylogeny studies (2019) has been reorganized into seven genera, as indicated above. A second new subfamily, *Hamaparvovirinae*, was created and accommodates densoviruses in three of the five genera which infect invertebrates namely genera, *Brevihamadensovirus* (originally *Brevidensovirus*), *Hepanhamadensovirus* (originally *Hepandensovirus*) and *Penstylhamadensovirus* (originally *Penstyldensovirus*).

Densoviruses were first discovered in the early 1960s as an epizootic of denosonucleosis (the name reflecting the dense appearance of nuclei due to the accumulation of viroplasm in nuclei of infected cells) in a commercial mass rearing of the greater wax moth larvae used for fishing bait in France. The virions have a naked icosahedral $T = 1$ symmetry measuring 21–26 nm in diameter with a monopartite ssDNA genome, 4–6 kb in length encoding two or three NS proteins and two to four VPs depending on the species. The ambisense densoviruses (in the seven ambidensovirus genera) package both the –ve and +ve ssDNA strands, but in separate virions while the other, monosense capsids, package primarily the -ve ssDNA strand. The imperfect palindromic sequences at each end of the genome fold into hairpins providing a free 3' OH for initiating DNA replication using host DNA polymerase. There is a wide variety of expression strategies to generate the different proteins, including splicing, leaky scanning and overlapping promoters and ORFs. As a group, the densoviruses have a very broad host range, including six orders of insects, decapod crustaceans, like shrimp and crayfish and echinoderms, like starfish. Parvovirus infections are polytropic in the tissues they infect and are often lethal and spread easily. Disease can be devastating to commercial enterprises, especially in industrial shrimp and crayfish farming, silk production and in the insects for food industry such as cricket farming. Some insect parvoviruses might be potentially developed as biocontrol agents against insect pests like ants and mosquitoes and perhaps some agricultural insect pests. For example, densovirus was used to successfully control *Limacodidae* pests of oil palm plantations and *Galleria mellonella* in beehives.

Polydnaviridae

Family: *Polydnaviridae* [ICTV 1984]

Genus: *Bracovirus* [ICTV 1999] (32 species)

Type Species: *Cotesia melanoscela bracovirus* [ICTV 1990]

Species Exemplar: *Cotesia melanoscela bracovirus*

Genus: *Ichnovirus* [ICTV 1990] (21 species)

Type Species: *Campoletis sonorensis ichnovirus* [ICTV 1999]

Species Exemplar: *Campoletis sonorensis ichnovirus*

Polydnaviruses were first recognized in the late 1970s in the laboratories of Don Stoltz (Dalhousie University, Canada) and Brad Vinson (Texas A&M University, USA) who noticed virus-like particles from the calyx region of the ovaries of first *Apanteles* (later renamed *Cotesia*) *melanoscelus* and then in other parasitic hymenoptera. Polydnaviruses are associated with the reproductive tracts of braconid (bracoviruses) and ichneumonid (ichnoviruses) parasitoids. Injected, along with parasitoid eggs, into host caterpillars, polydnaviruses subvert the host immune and physiology systems benefiting developing parasitoid eggs and larvae. Polydnaviruses are also characterized as having a multipartite circular dsDNA genome, referred to originally as a polydisperse genome, from which the family *Polydnaviridae* took its name. Because of the distinct differences, particularly in morphology and phylogeny between polydnaviruses from braconid wasps and those from ichneumonid ones, the viruses were classified in two genera *Bracovirus* and *Ichnovirus*, respectively. Another unique feature of polydnaviruses is that their genomes exist in an integrated and extrachromosomal form. The integrated provirus form allows for vertical transmission, and some of the integrated genes are responsible for generation of virions in the calyx cells. The extrachromosomal form is packaged into virions and encodes genes expressed to take over host immunology and physiology to benefit the developing parasitoid subsequent to their delivery coincident with oviposition.

The polydnavirus virion DNA is a collection of discrete numbers of circular dsDNA molecules in non equimolar abundance. The number and size of individual circles varies depending on the genus and species.

Bracovirus virions measure 50 nm in diameter x 30–80 nm long, consist of rod-shaped nucleocapsids with one or more of them surrounded by a nucleus-derived membrane and resemble baculovirus budded viruses. It was because of this morphology that bracoviruses were originally classified along with the baculoviruses in 1982 with the bracovirus *Apanteles melanoscelus virus* (now *Cotesia melanoscelus polydnavirus*) being recognized as a species in the then genus *Baculovirus* in the family *Baculoviridae*. The bracovirus dsDNA genome consists of 15–30 circles ranging in size from 2 to 50 kb with aggregate sizes of 125–600 kb. BV nucleocapsids assemble and acquire an envelope from the nucleus forming intranuclear virions in calyx cells near the lumen. These “mature” calyx cells fill with virions, eventually rupturing the nuclear envelope and escaping into the calyx lumen when the cells disrupt.

Ichnoviruses have quite a different morphology. The lenticular nucleocapsid measures 80–90 nm in diameter x up to 300 nm in length. Single (from *Campopleginae* wasps) or multiple (from *Banchinae* wasps) nucleocapsids are surrounded by two, two-unit membranes, the inner one derived from within the nucleus, often surrounding a hook at one end and the outer one derived from the plasma membrane during budding into the calyx lumen. Ichnovirus circular dsDNA genomes consist of 20–50 circles ranging in size

from 2 to 38 kb with aggregate sizes of around 250 kb. Ichnovirus replication is similar to that of bracoviruses in that nucleocapsids assemble in a virogenic stroma in the nucleus where they also acquire an envelope. From that point ichnovirus development differs from the bracoviruses as the enveloped ichnovirus subvirions exit the nucleus and then bud into the calyx lumen through the apical plasma membrane.

There has been a flurry of research activity surrounding the nature of the integrated and extrachromosomal (virion) DNA, the origin of the genomes and the expression of viral genes within the parasitoid and following oviposition in the parasitized host. During virus production the viral DNA segments of the integrated genomes are amplified, excised and circularized prior to encapsidation into polydnavirus nucleocapsids destined for envelopment and secretion into the calyx lumen. The “replication” genes remain integrated but are amplified in calyx cells. They are then expressed to produce mostly proteins associated with virus production. Many polydnavirus genes are derived from the parasitoids which harbor them and consequently the phylogeny of the virus often reflects the phylogeny of the parasitoids which harbor them.

Poxviruses of Invertebrates (*Entomopoxvirinae*)

Family: *Poxviridae* [ICTV 1978] (Order *Chitovirales*, ICTV 2019)

Subfamily: *Entomopoxvirinae* [ICTV 1978]

Genus: *Alphaentomopoxvirus* [ICTV 2004] (7 species)

Type Species: *Melonontha melonontha entomopoxvirus* [ICTV 1976]

Species Exemplar: *Melonontha melonontha entomopoxvirus*

Genus: *Betaentomopoxvirus* [ICTV 2004] (16 species)

Type Species: *Amsacta moorei entomopoxvirus* [ICTV 1976]

Species Exemplar: *Amsacta moorei entomopoxvirus*

Genus: *Deltaentomopoxvirus* [ICTV 2019] (1 species)

Type Species: *Melanoplus sanguinipes entomopoxvirus* [ICTV 1976]

Species Exemplar: *Melanoplus sanguinipes entomopoxvirus*

Genus: *Gammaentomopoxvirus* [ICTV 2004] (6 species)

Type Species: *Chironomus luridis entomopoxvirus* [ICTV 1976]

Species Exemplar: *Chironomus luridis entomopoxvirus*

Subfamily: *Chordopoxvirinae* [ICTV 1978]

Genus: *Centapoxvirus* [ICTV 2016] (2 species)

Type Species: *Yokapox virus* [ICTV 2016]

Species Exemplar: *Yoka poxvirus*

The *Poxviridae* family is subdivided into two subfamilies. Poxviruses of vertebrates, like the familiar smallpox virus, are classified in the subfamily *Chordopoxvirinae*, while those in the *Entomopoxvirinae* subfamily infect only insects. The *Entomopoxvirinae* subfamily is currently divided into three genera, *Alphaentomopoxvirus* with 7 species, *Betaentomopoxvirus* with 16 species and *Gammaentomopoxvirus* with 6 species. The entomopoxviruses, first discovered by Constantine Vago in 1963, have been isolated from four orders of insects, namely Coleoptera, Orthoptera, Lepidoptera and Diptera. One poxvirus, Yoka poxvirus, was isolated from pools of mosquitoes in 1972, but phylogenetically it is more similar to orthopoxviruses than to any entomopoxvirus. Yoka poxvirus is classified in the subfamily *Chordopoxvirinae*, *Centapoxvirus* genus, species *Yokapoxvirus*. Moreover, it replicates in Vero and other mammalian cells and causes death in intracranially-inoculated suckling mice suggesting it may not be an insect virus. Given that it was isolated from a pool of mosquitoes it is more likely to be a contaminant of a chordopoxvirus, perhaps from a blood meal. Entomopoxvirus virions are ovoid shaped measuring 140–260 nm × 220–450 nm with a complex morphology. The entomopoxvirus genome is a linear dsDNA ranging in size from 229 to 308 kb with an A+T content of 79%–82% and shares 49 core genes with the chordopoxviruses. Unlike the chordopoxviruses of vertebrates, entomopoxviruses are embedded in a spherical shaped spheroid, made of spheroidin, much in the same manner that baculoviruses are embedded in a polyhedrin or granulin based occlusion body.

Similar to other poxviruses, as described elsewhere in this encyclopedia, entomopoxviruses replicate in the cytoplasm in viroplasms, first as immature particles that mature into enveloped brick-shaped intracellular mature virions which can be released by cell lysis or by budding through the plasma membranes as external enveloped virions allowing systemic spread of the infection. Late in infection, and unlike chordopoxviruses, mature entomopoxvirions become severally occluded in spheroids, remaining intracellular till cell lysis with the spheroids allowing for insect to insect spread. Another unique feature of entomopoxviruses is that they produce a viral protein called fusolin which can be occluded with virions into spheroids which can also result in the formation of “spindles” which are not occluded. The spindles are thought to disrupt the peritrophic membrane allowing access of the virus to the epithelial cells of the larval midgut. Fusion of the outer EPV membrane with the plasma membrane allows access to the cell cytoplasm where replication occurs. Virus spread in the insects starts with the hemocytes and spreads to the fat body, the main site for virus replication, and other tissues. The signs of the disease vary depending on the virus and the host. EPV-infected lesser cornstalk borer become unresponsive and sluggish with their cutical changing from brown to orange, while in black-soil scarabs they develop a white spotted or mottled epidermis. EPV-infected lepidoptera can become whitish while some increase in size due to delayed pupation. Although they are insect viruses that can kill the insect, the time to kill is too long to be feasible for use in the control of insect pests.

Reoviruses of Invertebrates (*Sedoreovirinae* and *Spinavirinae*)

Family: *Reoviridae* [ICTV 1974] (Order *Reovirales*, ICTV 2019)

Subfamily *Sedoreovirinae* [ICTV 2009]

Genus: *Cardoreovirus* [ICTV 2008] (1 species)

Type Species: *Eriocheir sinensis reovirus* [ICTV 2008]

Species Exemplar: *Callinectes sapidus reovirus* 1

Genus: *Phytoreovirus* [ICTV 1978] (3 species)

Type Species: *Wound tumor virus* [ICTV 1976]

Species Exemplar: *Wound tumor virus* (34)

Genus: *Seadornavirus* [ICTV 2004] (3 species)

Type Species: *Banna virus* [ICTV 1999]

Species Exemplar: *Banna virus-China*

Subfamily: *Spinavirinae* [ICTV 2009]

Genus: *Aquareovirus* [ICTV 1990] (7 species)

Type Species: *Aquareovirus A* [ICTV 1999]

Species Exemplar: *American oyster reovirus*13p2

Genus: *Coltivirus* [ICTV 2009] (5 species)

Type Species: *Colorado tick fever coltivirus* [ICTV 1974]

Species Exemplar: *Colorado tick fever-Florio*

Genus: *Cypovirus* [ICTV 1990] (16 species)

Type Species: *Cypovirus 1* [ICTV 1999]

Species Exemplar: *Bombyx mori cypovirus* 1

Genus: *Dinovernavirus* [ICTV 2008] (1 species)

Type Species: *Aedes pseudoscutellaris reovirus* [ICTV 2008]

Species Exemplar: *Aedes pseudoscutellaris reovirus*

Genus: *Idnoreovirus* [ICTV 2004] (5 species)

Type Species: *Idnoreovirus 1* [ICTV 2004]

Species Exemplar: *Diadromus pulchellus idnoreovirus* 1

Genus: *Orthoreovirus* [ICTV 1991] (10 species)

Type Species: *Mammalian orthoreovirus* [ICTV 1999]

Species Exemplar: *Mahlapitsi orthoreovirus*

The reoviruses have a broad host range, including insects, algae, fungi, fish, crustaceans, crabs as well as humans and other vertebrates and their invertebrate vectors and of plants and their invertebrate vectors. The *Reoviridae* family is subdivided into two subfamilies, *Sedoreovirinae* with six genera and *Spinavirinae* with nine genera. The two subfamilies differ in the nature of the virion surface with the *Spinavirinae* having a turreted or “spiked” surface (hence the prefix “Spina”, Latin for spike) while the *Sedoreovirinae* have a smooth surface (“Sedo” is Latin for smooth). Of the more recognized reoviruses are those infecting humans, other mammals and other vertebrates. Those from *Rotavirus* and *Orthoreovirus* genera infect only vertebrates, while viruses in genera *Coltivirus*, *Orbivirus* and *Seadornavirus* are considered arboviruses which infect both vertebrates and their insect vectors (mostly ticks, mosquitoes, midges, gnats and sandflies). Lesser known reoviruses infect algae (*Mimoreovirus*) and fungi (*Mycoreovirus*). In addition to infecting plants, reoviruses in genera *Fijivirus*, *Oryzavirus* and *Phytovirus* also infect their insect vectors (e.g., glassy winged sharpshooter). Reoviruses infecting only invertebrates are in genera *Cardoreovirus* (crabs), *Cypovirus* (insects), *Dinovernavirus* (mosquitoes) and *Idnoreovirus* (hymenoptera and diptera). The aquareoviruses, as the name implies, infect aquatic vertebrates like fish and but also aquatic invertebrates including shellfish and crustaceans such as oysters.

This summary includes six genera of invertebrate-infecting reoviruses, *Cardoreovirus*, *Phytoreovirus* and *Seadornavirus* in the *Sedoreovirinae* and *Cypovirus*, *Dinovernavirus* and *Idnoreovirus* in the *Spinavirinae*. Of the *Spinavirinae* insect reoviruses, most cypoviruses have 10 dsRNA segments and infect lepidopteran insects like *Lymantria dispar* (Gypsy larvae), idnoreovirus have 10 dsRNA segments and infect *Diadroma pulchella* (a hymenopteran parasitoid) and dinovernavirus has 9 dsRNA segments and infects *Aedes* mosquitoes. Most of the *Sedoreovirinae* reoviruses have 12 dsRNA segments (though *Macrobrachium nipponense reovirus* has 10 dsRNA segments). Seadornavirus is an arbovirus of humans, pigs and cattle but also infects mosquito vectors and two seadornaviruses appear to infect only mosquitoes.

As noted some reoviruses, like the arboviruses in the genera *Coltivirus* (Colorado tick fever virus), and *Orbivirus* (Bluetongue virus) are vectored by invertebrates which themselves are infected and include midges, mosquitoes, ticks and sandflies. Also, some reoviruses infect plants and are vectored by invertebrates carrying the viruses. These are described in more detail in other articles in this Encyclopedia.

Like other reoviruses, most invertebrate reoviruses have a double shelled icosahedral capsid with diameters ranging from 60 to 80 nm (though idnoreovirus capsids are smaller at about a 50 nm diameter). While cypoviruses and dinovernaviruses have a single shell with $T = 2$, aquareoviruses, coltiviruses, idnoreoviruses, cardcoreoviruses, phytoviruses and seadornaviruses have two shells, the inner with $T = 2$ and the other with $T = 13$ icosahedral symmetry. As noted above they have 9–12 dsRNA segments. These range in size from 0.76 to 4.8 kb with each segment, except for cypoviruses, encoding one protein. For cypoviruses, segment 5 encodes two proteins by ribosomal skipping.

Cypovirus was the first invertebrate reovirus discovered and that was in 1934 as polyhedra in the cytoplasm of infected cells of silkworm larvae and hence were initially named cytoplasmic polyhedrosis viruses from which the current genus name was derived.

Aquareoviruses (*Aqua* for their common aqueous environment of their hosts) have been isolated from oysters and crabs. Coltiviruses (from *Colorado tick fever virus*) replicate in ticks as well as mammalian hosts. Idnoviruses (from “idno” meaning water) were first isolated from houseflies in 1978, while the lone dinovernavirus (from *double stranded RNA icosahedral nove*, meaning nine, dsRNA segments) was isolated from a cell line from *Aedes pseudoscutellaris* in 2005. The first cardoreovirus (from *carcinus* for crab and *dodeca* for 12 dsRNA segments) was isolated in 2004 from diseased mitten crabs (*Eriocheir sinensis*). The Banna virus, in the genus *Seadornavirus* (from Southeast Asian *dodeca* for 12 dsRNA segments), was first discovered in 1987 in a patient with encephalitis and fever in China. Phytoreoviruses (from “phyto” Greek for plant) were initially discovered in 1941 as wound tumor viruses of plants transmitted by leaf hoppers in which the virus also replicates.

The invertebrate reoviruses range from having a limited host range to a broad one. Aquareoviruses have been isolated from American oyster and Geoduck, shore, swimmer and mitten crabs. Coltiviruses replicate in ticks, the main vector for Colorado tick fever and mosquitoes. Cypoviruses have been isolated from lepidoptera and hymenoptera. Idnoreoviruses infect hymenoptera, and dipterans like the housefly, olive fly and fruit flies. So far dinovernavirus has been isolated solely from persistently infected *Aedes pseudoscutellaris* cells. Seadornaviruses have been found in mosquitoes, cardoreovirus in crabs and prawn and phytoreovirus in various plants and leafhopper vectors.

Infection and replication of the invertebrate reoviruses closely mimic that of other reoviruses, so the reader is referred to other reovirus chapters. One unique feature of the cypoviruses is that they form polyhedra which can retain infectivity for years. The major polyhedrin protein is translated in the cytoplasm late in infection in large excess and virions are occluded in the polyhedrin at the periphery of the virogenic stroma in which morphogenesis of the virions occurs.

Rhabdoviruses of Invertebrates (*Rhabdoviridae*, *Almendravirus*, *Alphanemrhavirus*, *Caligrhavirus*, *Sigmavirus*)

Family: *Rhabdoviridae* (Order *Mononegavirales*, ICTV 1990)

Genus: *Almendravirus* [ICTV 2016] (6 species)

Type Species: *Puerto Almendras almdravirus* [ICTV 2016]

Species Exemplar: Puerto Almendras virus (Lo-39)

Genus: *Alphanemrhavirus* [ICTV 2018] (2 species)

Type Species: *Xingshan alphanemrhavirus* [ICTV 2018]

Species Exemplar: Xingshan nematode virus 4 (XSNXC3292)

Genus: *Caligrhavirus* [ICTV 2018] (3 species)

Type Species: *Lepeophtheirus caligrhavirus* [ICTV 2018]

Species Exemplar: *Lepeophtheirus salmonis* rhabdovirus 127 (LSRV127)

Genus: *Sigmavirus* [ICTV 2012] (7 species)

Type Species: *Drosophila melanogaster sigmavirus* [ICTV 2012]

Species Exemplar: *Drosophila melanogaster* sigmavirus (HAP23)

Like reoviruses, rhabdoviruses as a group, composing 30 genera, have a very broad host range, including humans and other mammals (e.g., genera *Lyssavirus*, *Tibrovirus*, *Vesiculovirus*), fish (genera *Novirhabdovirus*, *Perhabdovirus* and *Sprivivirus*), birds (genus *Tupavirus*) and plants (*Varicosavirus* nucleorhabdoviruses). Many of the vertebrate rhabdoviruses, (like those in genera *Curiovirus*, *Ephemerovirus*, *Tibrovirus* and *Vesiculovirus*) are also arboviruses that have been isolated from arthropod vectors like mosquitoes, midges and ticks. The arthropod specific rhabdoviruses belong to four genera in the *Rhabdoviridae* family, *Almendravirus* with five species, *Alphanemrhavirus* with two species, *Caligrhavirus* with three species and the most studied *Sigmavirus*, with seven species. Not covered in this introductory section are some rhabdoviruses in other genera that are arboviruses which infect vertebrates and are found in arthropod vectors such as midges, sandflies and mosquitoes and those found in insects such as aphids, planthoppers, leafhoppers and mites that transmit virus to plants, but do not replicate in the vector. The higher-level taxonomic designation of these viruses is highly convoluted but for the sake of completeness, these viruses belong to the Order *Mononegavirales*, Class *Monjiviricetes*, Subphylum *Haploverticota*, Phylum *Negarnaviricota* and Realm *Riboviria*.

In terms of morphology and virus replication the insect rhabdoviruses are similar to other rhabdoviruses covered elsewhere in this Encyclopedia. They have a helical nucleocapsid, surrounded by an envelope with spikes and a matrix between the nucleocapsid and envelope. The bullet shaped virions measure 80 nm diameter x 100 nm in length (sigmaviruses) or 40–55 nm diameter x 190–460 nm in length (almendraviruses). Alphanemrhavirus was identified only through metagenomic sequencing of pooled parasitic nematode populations, so it is not sure if an infectious virion form exists for this species.

The 10.5–14.5 kb ssRNA genome encodes in a 3′ to 5′ direction the canonical four rhabdovirus structural genes for, nucleoprotein (N) which is the major protein of the nucleocapsid, phosphoprotein (P) which ensures proper placement of L on the genome, matrix protein (M) which is the major structural protein between the nucleocapsid and virion and helps regulate genome RNA synthesis, and, glycoprotein G which is the major envelope glycoprotein and acts as the virus attachment protein and the non structural large protein (L) which is responsible for RdRp activity, 5′ capping and 3′ polyadenylation. In addition, the genomes of sigmavirus has an additional ORF X between P and M, involved in host-virus interaction and in almdravirus encodes an additional class 1a viroporin, between G and L. In some cases, such as sigmaviruses, invertebrate rhabdovirus sequences are found integrated into the genomes of drosophila and some mosquitoes.

The insect rhabdovirus life cycle is similar to that of other rhabdoviruses. Virions attach to host cell receptors through the G glycoprotein inducing low pH-dependent receptor-mediated endocytosis. Transcription occurs in the cytoplasm in a “stop start” L and P dependent process to generate separate monocistronic mRNAs for each of the proteins in decreasing molar abundance from the 3' to 5' end of the genome. Each mRNA has a common leader 5' end which is 5' capped and ending in a reiterative copying-derived polyA at the 3' end. Late in infection, following translation of viral proteins and when the concentration of N protein has increased to sufficient levels, transcription switches to genome replication. During genome replication the full length antigenome +ve ssRNA template is produced and serves as the replicative intermediate for full length -ve sense genome ssRNA. The genome ssRNA is then encapsidated in N protein in a P protein dependent fashion. The formed nucleocapsids and M protein attach to the plasma membrane of infected cells and bud through it to release mature virions which can then infect adjacent cells.

Invertebrate rhabdoviruses have been found in several insects such as fruit flies, butterflies, mosquitoes and bees, as well as in nematodes and sea lice copepods. For the most part, transmission is vertical through either the female or male parents, though for sigmaviruses they can be experimentally transmitted by injection.

Roniviridae

Family: *Roniviridae* [ICTV 2002] (Order *Nidovirales*, ICTV 1996)

Subfamily: *Okavirinae* [ICTV 2018]

Genus: *Okavirus* [ICTV 2002] (3 species)

Subgenus: *Tipravirus* [ICTV 2018]

Species: *Gill-associated virus* [ICTV 2002]

Species Exemplar: Yellowhead virus

To date all roniviruses (from “rod shaped nidovirus”) are from crustaceans, the prawn *Penaeus monodon*. Two viral diseases are associated with roniviruses, one caused by Yellowhead virus in black tiger shrimp which first appeared in Thailand in 1990 and the second, Eriocheir sinensis ronivirus which causes black gill disease in Chinese mitten crab. Yellowhead virus appears to be transmitted horizontally, while gill-associated virus can be transmitted vertically. Roniviruses differ from other nidoviruses in having a bacilliform 40–60 nm × 150–200 nm enveloped virion. Like other nidoviruses it has a long, 26 kb, +ve ssRNA monopartite genome. The ronivirus genome encodes a 5' terminal replicase complex (ORF1) followed by ORF2 for p20 nucleoprotein, ORF3 for pp3 (producing gp116 and gp64 envelope glycoproteins) and ORF4 of unknown function. The replicase ORFs ORF1a and ORF1b have a slippery sequence and RNA pseudoknot allowing for a – 1 ribosomal frameshift and read through to a pp1ab replicase. Unlike other nidoviruses, roniviruses (and toroviruses) lack the common 5' leader. Preceding ORFs 2 and 3 are intergenic regions (IGRs) acting as a terminator and promoter. Replication probably follows that of other nidoviruses, like coronavirus described elsewhere, to generate a nested set of subgenomic mRNAs. Unlike other nidoviruses that use a discontinuous strategy to generate the different sgRNAs, roniviruses appear to use a “continuous” transcription strategy.

Sarothroviridae

Family: *Sarothroviridae* [ICTV 2015]

Genus: *Macronovirus* [ICTV 2015] (1 species)

Type Species: *Macrobrachium satellite virus 1* [ICTV 2015]

Species Exemplar: Extra small virus

Extra small virus (XSV) derives its name based on the extremely small size of its naked icosahedral particle, of about 15 nm in diameter, with the name sarthrovirus derived from small *arthropod* virus. These viruses are +ve ssRNA satellite viruses, depending on their replication on the RdRp of *Macrobrachium rosenbergii* nodavirus (MrNV). XSV belongs to the sole and type species *Macrobrachium satellite virus 1*, in the single genus *Macronovirus* of the family *Sarothroviridae*. They affect mostly different species of prawns, but have also been isolated from crayfish, beetles and water bugs and replicate in mosquito cell lines suggesting mosquitoes might be a vector. The genomic RNA is +ve sense, 796 ntd in size with a 3' polyA tail and an upstream polyadenylation signal. It encodes two ORFs for coat proteins CP16 and CP17 made in equimolar amounts, with the ORF for CP16 initiating at an internal methionine codon. Infected prawns present with lethargy and opaqueness of the abdominal muscle and degeneration of the telson and uropods, followed by death around five days after observation of gross signs of infection. Immersion in a mixture of MrNV and XSV results in 100% mortality by 12 days post infection. They are a major problem for the shrimp farms in China, India, Australia, French West Indies, Taipei and Thailand.

Solinviviridae

Family: *Solinviviridae* [ICTV 2016] (Order *Picornavirales*, ICTV 2008)

Genus: *Invictavirus* [ICTV 2016] (1 species)

Type Species: *Solenopsis invicta virus 3* [ICTV 2016]

Species Exemplar: *Solenopsis invicta virus* (DM)

Genus: *Nyfulvavirus* [ICTV 2016] (1 species)

Type Species: *Nylanderia fulva virus 1* [ICTV 2016]

Species Exemplar: *Nylanderia fulva virus 1* (Florida initial)

Soliniviruses were first discovered through a bioprospecting approach using metagenomics of ant populations, showing the value of this approach to identify novel and perhaps useful biological control agents. Soliniviruses are icosahedral in shape measuring 27–29 nm in diameter with $T = 3$ symmetry and showing surface projections and cup-like depressions. The virions are composed of two capsid proteins, VP1 and a VP1 fused to the capsid projection domain, CPD (VP1-CPD) and an about 10 kb +ve ssRNA genome with a 5' VPg and a 3' polyA tail. The genome encodes a single polyprotein ORF (*Nylanderia fulva* virus) or two polyprotein ORFs via frame shifting (*Solenopsis invicta* virus). The polyprotein for the nonstructural proteins, helicase, protease and RdRp, are located at the amino end of the polyprotein while the structural proteins VP1 (or VP1-CPD) and VP2 are at the carboxy ends. It is thought that the polyprotein is cleaved to the individual proteins by the viral protease, much like poliovirus polyproteins are. There is some evidence of subgenomic mRNAs for the structural proteins.

Viruses enter the host by feeding to access the alimentary canal of larval stage ants (*NflV-1*) or adults (*SINPV-3*). Based on the genome organization, replication is thought to be similar to that of polioviruses and caliciviruses. Replication is in the cytoplasm with the genomic +ve ssRNA acting as a transcript and later as a template for the production of genome length –ve sense ssRNA replicative strand. Virus assembly presumably occurs by encapsidation of the genomic +ve sense ssRNA by the viral capsid proteins. Virus spread is intercolonial through trophallaxis. Soliniviruses are specific to *Solenopsis* genera fire ants which exhibit signs of infection including Queen weight decline, reduced feeding and fecundity and larval mortality. Virus can be transmitted mechanically by consumption of crickets that consume dead, SIV-3-infected worker ants. Soliniviruses are being developed as biological control agents using protein baits with lower doses resulting in chronic infection and higher doses of 10^7 to 10^9 virus particles per ml leading to colony collapse. The major problem for biopesticide development is the production of sufficient virus.

Tetraviruses (Families, *Alphatetraviridae*, *Carmotetraviridae*, *Permutotetraviridae*)

Family: *Alphatetraviridae* [ICTV 2016] (Order *Hepelivirales*, ICTV 2019)

Genus: *Betatetravirus* [ICTV 1997] (7 species)

Type Species: *Nudaurelia capensis beta virus* [ICTV 1995]

Species Exemplar: *Nudaurelia cytheria capensis* β virus

Genus: *Omegatetravirus* [ICTV 1997] (3 species)

Type Species: *Nudaurelia capensis omega virus* [ICTV 1995]

Species Exemplar: *Nudaurelia capensis* ω virus

Family: *Carmotetraviridae* [ICTV 2011] (Order *Tolivirales*, ICTV 2019)

Genus: *Alphacarmotetravirus* [ICTV 2011] (1 species)

Type Species: *Providence virus* [ICTV 2004]

Species Exemplar: *Providence virus*

Family: *Permutotetraviridae* [ICTV 2011]

Genus: *Alphapermutotetravirus* [ICTV 2011] (2 species)

Type Species: *Thosea asigna virus* [ICTV 2004]

Species Exemplar: *Thosea asigna virus*

The tetraviruses were all at one time members of the *Tetraviridae* family with the common features of a unique $T = 4$ icosahedral symmetry, a common jelly roll architecture of the capsid protein which form a monophyletic group all infecting insects and all having a +ve sense ssRNA genome with a VPg at the 5' end and a polyA tail at the 3' end. However, there are some features which differed among the original species in the family, particularly the nature of the 3' end, existence of either a mono or bipartite genome, phylogeny of the RdRp of the tetraviruses and nature of the ORFs and their translation. In particular the alphatetraviruses (family *Alphatetraviridae*) have a monopartite (*Betatetravirus* genus) genome encoding both the replicase and through a subgenomic RNA the capsid protein and ending in a structured 3'tRNA-like end or a bipartite (*Omegatetravirus* genus) genome one encoding a replicase and the other the capsid protein. The replicase of both genera are alpha-like Supergroup replicases. Viruses in family *Carmotetraviridae* have a monopartite genome with one ORF encoding a Carmo-like supergroup replicase generated by a read through stop signal and the second ORF a capsid ORF generated from a subgenomic RNA. The permutotetraviruses, also have a monopartite genome with a highly structured 3' terminal sequence. The replicase and VPg are like those in the dsRNA bimaviruses including a permuted active site, hence the family name *Permutotetraviridae*.

Except for the, perhaps, subtle differences particularly in RdRp phylogeny and genome organization, most other characteristics are shared so these viruses are here treated collectively as tetraviruses. The monopartite genomes of the betatetraviruses of the *Alphatetraviridae*, carmotetraviruses, and permutotetraviruses are 6.6, 6.2, and 5.7 kb in size. Those of the bipartite genomes of the omegaviruses of the *Alphatetraviridae* are about 2.4 and 5.3 kb in size with the larger one encoding at least replicase and the smaller one encoding capsid protein ORFs. The capsid proteins are derived from subgenomic RNAs from the gRNA of either the monopartite genomes or the smaller omegavirus gRNA. The iconic $T = 4$ icosahedral capsid is about 40 nm in diameter and made from capsid proteins from all tetraviruses being monophyletic. While they usually encapsidate viral RNA, the capsids can also capsidate non-viral RNAs, allowing for generation of reassortant viruses and gene exchange. When just capsid proteins are expressed, in a baculovirus expression system, they self-assemble and under acidic conditions condense to tetravirus-like VLPs. It has long been thought that tetraviruses replicate only in insects (particularly midgut cells of larvae) and cell culture but it was recently shown that they also infect and replicate in lab-infected HeLa and MCF7 cancer cells, as well as in cowpea plants. They are found mostly as persistent infections.

Taxa of Other Viruses of Invertebrates

Not included in these summary descriptions above of viruses of invertebrates are taxa for which little is known and those for whose designations have relied largely on only sequence data from next generation high throughput sequencing and metagenomic studies of environmental samples. For many of these, if they are actually viruses of insects have not been otherwise confirmed. Since environmental samples were the source of the sequences the nucleic acid might simply have been a contaminant, or even present due to a blood meal from infected animals. While sequence data can predict phylogeny and protein composition, except for the source of the material which was analyzed, it cannot accurately provide information on basic virological data such as morphology, replication cycle, biological characteristics and true hosts. Below is a listing of some of these taxa along with some minimal associated information.

Circoviridae [ICTV 1993] (Order *Cirivirales*, ICTV 2019) hosts two genera, *Circovirus* [ICTV 1993] and *Cyclovirus* [ICTV 2015]. Circoviruses are characterized by having a circular, 1.7–1.9 kb ssDNA genome within an icosahedral capsid with $T = 1$ symmetry. The monopartite covalently closed ssDNA genome is ambisense encoding two proteins, capsid protein and replication associated protein for rolling circle DNA replication. Two of the most known circoviruses are the porcine circovirus and beak and feather disease virus of parrots. Commercially available vaccines like CircoFLEX, Circogard and Circumvent PCV2 G2, derived from virus-like particles synthesized by the insect baculovirus expression vector system, are effective against some porcine circovirus infections. While viruses from most species in both genera of the *Circoviridae* family infect humans, other mammals and birds, some virus sequences are associated with spiders and insects including ants, mosquitoes cockroaches and dragonflies. All of the insect-specific species, like *ant associated cyclovirus 1* are referred to as “associated cyclovirus” or “associated circovirus”. This is because the viruses have been identified solely through virus discovery approaches using next generation sequencing or metagenomics approaches. Consequently, we have no information about the true nature of these viruses.

Genomoviridae [ICTV 2015] (Order *Gepfluvirales*, ICTV 2019) genus *Gemyduguivirus* [ICTV 2016], with the single and type species *Dragonfly associated gemyduguivirus 1*, genus *Gemykibivirus* [ICTV 2016], with 16 species including the type species *Dragonfly associated gemykibivirus* [ICTV 2016], and genus *Gemycircularvirus* [ICTV 2015] with 43 species including species *Dragonfly associated gemycircularvirus* and *mosquito associated gemycircularvirus* are all associated with dragonflies and mosquitoes. Genomoviruses, at least for those based on more than sequence analyses, and despite being in a different order are similar to circoviruses in having a circular ambisense ssDNA genome encoding Rep and Capsid proteins in an icosahedral capsid with $T = 1$ symmetry. The genome is 2.2 kb in size and the capsids measure 29 nm in diameter. Following entry to the cytoplasm the genomovirus DNA becomes double stranded and replication is thought to be by a rolling circle mechanism. They are associated with a broad range of sources including invertebrates, humans, other mammals, birds and fungi.

Lispiviridae [ICTV 2018] (Order *Mononegavirales*, ICTV 1990) family has a single genus, *Arlivirus* [ICTV 2015] with six species, *Lishi arlivirus* [ICTV 2015] being the type species. Viruses in this family have a –ve ssRNA genome and are associated with spiders. Based on the sequence from Lishi spider virus 1 from China the lispivirus genome is bisegmented –ve ssRNA. The larger segment is 7,051 ntd in size and encodes the L protein, while the smaller one, 4,426 ntd in size encodes the G, N and VP4 proteins. As the only evidence provided for this virus is through genome sequencing, there is no further information on, for example virion morphology, replication cycle, transmission or host range.

Phasmaviridae [ICTV 2016] (Order *Bunyavirales*, ICTV 2016), genus *Sawatrivirus* [ICTV 2018] with a single and type species, *Sanxia sawatrivirus* [ICTV 2018] from the Sanxia water strider-2 virus is associated with water strider insects. Genus *Orthophasmavirus* [ICTV 2016] viruses infect mosquitoes, cockroaches and midges. The genome is tripartite -ve ssRNA with S (for N protein), M (for G protein) and L (for L protein, RdRp) segments with sizes of 1.7, 5.2 and 6.8 kb, respectively. Virions in the family are spherical about 80 nm diameter and are enveloped. Genus *Jonvirus* [ICTV 2018] and *Feravirus* (from Ferak Virus) [ICTV 2018] viruses were initially isolated from *Aedes* cell line C6/36 from pools of mosquitoes collected in 2004 in the Tai National forest from Côte d'Ivoire. Both show typical bunyavirus morphology, except that Jonvirus also exhibits as enveloped rods measuring 60 nm by up to 600 nm (the genus name *Jonvirus* refers to Jonchet, a French pick-up sticks game where the shape of the sticks mimicked this unusual morphology).

Polycipiviridae [ICTV 2017] (Order *Picornavirales*, ICTV 2008) has three genera, *Chipocyclovirus*, *Hupolycivivirus* and *Sopolycivivirus*, [ICTV 2017]. The viruses are thought to be about 33 nm in diameter, icosahedral in shape with pseudo $T = 3$ symmetry and a 10–12 kb monopartite +ve ssRNA genome. Genomes of chipocycloviruses were isolated from midges like *Chironomus riparias*, while those of sopolyciviruses were isolated from a variety of ant species. Most of the information on this family is based on large scale sequencing of environmental samples and metagenomic approaches so little is known of the biology of its members, like morphology and replication strategy.

Phenuiviridae [ICTV 2016] (Order *Bunyavirales*, ICTV 2016) viruses contain a tripartite –ve ssRNA genome in an RNP structure within an enveloped virion, 80–120 nm in diameter and surface proteins organized in a $T = 12$ icosahedral structure. Some members of the family infect insects. Viruses from genus *Wenivirus* [ICTV 2018] with a single and type species *Shrimp wenivirus* [ICTV 2018] is associated with shrimp. Genus *Goukovirus* [ICTV 2016] (from Gouléako Village where it was first found) viruses and Genus *Phasivirus* [ICTV 2016] viruses are found exclusively in mosquitoes. Genus *Phlebovirus* [ICTV 1981] viruses infect mosquito vectors of some viruses in this genus.

Tospoviridae [ICTV 2018] (Order *Bunyavirales*) is a family of plant viruses. One genus in the family, *Orthotospovirus* [ICTV 2016] which includes the Tomato spotted wilt tospoviruses consists of viruses which replicate in the midgut of thrip vectors of the virus. After replication, the virus moves to the salivary glands from where it can be transmitted to plants. Like other bunyaviruses, these viruses are pseudocircular in shape with a tripartite -ve ssRNA genome of 3, 4.8 and 8.8 kb in size.

Xinmoviridae [ICTV 2018] (Order *Mononegavirales*, ICTV 1990) family has a single genus, *Anphevirus* [ICTV 2015] with seven species, with *Xincheng anphevirus* being the type species. The sequence of the viral genome of Xincheng mosquito virus is a monopartite 12,774 ntd

Table 2 Families of viruses with an invertebrate arthropod host and mammalian host, often causing human diseases

Family	Genus, type species (number of species in genus)	Genome type and size	Morphology	Invertebrate vector
<i>Asfarviridae</i> (<i>Asfuvirales</i>) ^a	<i>Asfivirus</i> , African swine fever virus (1)	dsDNA, linear, 170 to 194 kb	Spherical, 175 to 215 nm diameter, with icosahedral capsid core (170 to 190 nm diameter), internal and external envelope	Soft ticks (<i>Ornithodoros</i>), psyllids, odonates
<i>Flaviviridae</i> (<i>Amarillovirales</i>)	<i>Flavivirus</i> , Yellow fever virus (53)	+ ve ssRNA, 9 to 13 kb	Spherical, 40 to 60 nm diameter, enveloped	Mosquitoes, ticks
<i>Nairoviridae</i> (<i>Bunyavirales</i>)	<i>Orthonairovirus</i> , Dugbe orthonairovirus (15)	– ve ssRNA, tripartite, 1 to 3 kb; 3.2 to 4.9 kb; 6.8 to 12 kb	Spherical, 80 to 120 nm, enveloped	Ticks, crustaceans, nematodes
<i>Nyamiviridae</i> (<i>Mononegavirales</i>)	<i>Nyavirus</i> , Nyamanini nyavirus (3)	– ve ssRNA, 1 or 2 segments, total 12.2 kb	Spherical, 100 to 130 nm, enveloped	Ticks
<i>Orthomyxoviridae</i> (<i>Articulavirales</i>)	<i>Socycivirus</i> , Soybean cyst nematode socycivirus (1)	– ve ssRNA, tripartite, 6 to 7 segs 0.9 to 2.3 kb	Spherical, 80 to 120 nm diameter	Mosquitoes, sand flies
<i>Peribunyaviridae</i> (<i>Bunyavirales</i>)	<i>Quaranjavirus</i> , Quarafil quaranjavirus (2)	– ve ssRNA, tripartite, 1, 4 and 6 to 8 kb	Pleomorphic to spherical, 80 to 120 nm diameter	Mosquitoes, cockroaches water striders, drosophila, midges
<i>Phasmaviridae</i> (<i>Bunyavirales</i>)	<i>Thogotovirus</i> , Thogoto thogotovirus (2)	– ve ssRNA, tripartite, 1.5, 4.2 and 6.8 kb	Spherical, 80 to 120 nm diameter	Mosquitoes
<i>Phenuiviridae</i> (<i>Bunyavirales</i>)	<i>Orthobunyavirus</i> , Bunyamwera orthobunyavirus (88)	– ve ssRNA' tripartite 1,7, 3.2, 6.4 kb	Spherical, 80 to 120 nm diameter, surface envelope with T=12 symmetry	Mosquitoes, midges, gnats, sand flies, ticks
<i>Reoviridae</i> <i>Sedoreovirinae</i> (<i>Reovirales</i>)	<i>Orbivirus</i> , Bluetongue virus (22)	dsRNA, segmented	Orbi-icosahedral T=2/T=13, 80 nm diameter	Ticks, mosquitoes
	<i>Seadornaviru,s</i> Banna virus (3)	Orbi-10 segs, 0.8 to 4.0 kb Seado-12 segs 0.9 to 4.0 kb	Seado-icosahedral T=2/T=13, 60 to 70 nm diameter	
<i>Reoviridae</i> <i>Spinavirinae</i> (<i>Reovirales</i>)	<i>Coltivirus</i> , Colorado tick fever coltivirus (5)	12 segments, 0.7 to 4.4 kb	Icosahedral T=2/T=12 60 to 80 nm diameter	
<i>Rhabdoviridae</i> (<i>Mononegavirales</i>)	<i>Curiovirus</i> , Curionopolis curiovirus (41)	– ve ssRNA, 10.7 to 16.1 kb	Bullet shaped, rod shaped nucleocapsid 45 to 100 nm × 100 to 430 nm with matrix and envelope	Mosquitoes, midges, sandflies, ticks, fleas, blackflies
	<i>Ephemerovirus</i> , Bovine fever ephemerovirus (8)			Vertebrate hosts, mammalian, avian, lizards, reptiles
	<i>Hapavirus</i> , Flanders hapavirus (16)			
	<i>Ledantevirus</i> , Le Dantec ledantevirus (16)			
	<i>Sripuvirus</i> , Niakha sripuvirus (8)			
	<i>Tibrovirus</i> , Tibrogargan tibrovirus (7)			
	<i>Vesiculovirus</i> , Indiana vesiculovirus (16)			
<i>Togaviridae</i> (<i>Martellivirales</i>)	<i>Alphavirus</i> , Sindbis virus (31)	+ ve ssRNA, 10 to 12 kb	Spherical, 65 to 70 nm enveloped	Mosquitoes, ticks, lice

^aThe taxon Order is in brackets below the family or subfamily name. The number of species in each genus is given in brackets after the genus name.

Table 3 Some common arboviruses, taxonomy, listed by Order, vertebrate host and their invertebrate vectors

Arbovirus	Order	Family	Genus	Vertebrate host	Insect and arachnid vectors
Bagaza virus	Amarillovirales	Flaviviridae	Flavivirus	Game birds	Culex mosquitoes, midges
Entebbe bat virus	Amarillovirales	Flaviviridae	Flavivirus	bats	Mosquitoes
Dengue hemorrhagic fever virus	Amarillovirales	Flaviviridae	Flavivirus	Humans, primates	Aedes aegypti and Aedes albopictus, mosquitoes,
Japanese encephalitis virus	Amarillovirales	Flaviviridae	Flavivirus	Humans, wading birds, pigs, horse	Culex mosquitoes
Kyasanur forest disease virus	Amarillovirales	Flaviviridae	Flavivirus	Camels, rodents, monkeys	Hyalomma hard ticks
Louping ill virus	Amarillovirales	Flaviviridae	Flavivirus	Grouse, sheep	Ixodes ricinus ticks
Murray Valley encephalitis virus	Amarillovirales	Flaviviridae	Flavivirus	Humans, Ardeid water birds	Culex annulirostris mosquitoes
Powassan virus	Amarillovirales	Flaviviridae	Flavivirus	Humans	Ixodes and Dermacentor ticks
Spondweni virus	Amarillovirales	Flaviviridae	Flavivirus	Humans	Aedes circumluteolus mosquitoes
Saint Louis encephalitis virus	Amarillovirales	Flaviviridae	Flavivirus	Humans, birds	Culex pipiens mosquitoes
Tick-borne encephalitis virus	Amarillovirales	Flaviviridae	Flavivirus	Humans, rodents	Ixodidae ticks
West Nile virus	Amarillovirales	Flaviviridae	Flavivirus	Humans, birds, horse	Culex mosquitoes
Yellow fever virus	Amarillovirales	Flaviviridae	Flavivirus	Humans, primates	Aedes, Hemagogus and Sabethes mosquitoes
Zika virus	Amarillovirales	Flaviviridae	Flavivirus	Humans, primates	Aedes mosquitoes
Thogoto virus	Articulavirales	Orthomyxoviridae	Thogotovirus	Humans, wild and domestic vertebrates	Hyalomma hard ticks
African swine fever virus	Asfarvirales	Asfarviridae	Asfivirus	Pig, warthog, bushpig	Ornithodoros soft ticks,
Bunyamwera virus	Bunyavirales	Peribunyaviridae	Orthobunyavirus	Humans	Aedes aegypti mosquitoes
California encephalitis virus	Bunyavirales	Peribunyaviridae	Orthobunyavirus	Humans	Mosquitoes
Crimean-Congo fever virus	Bunyavirales	Nairoviridae	Orthonairovirus	Humans, wild and domestic animals	Hyalomma hard ticks
Jamestown Canyon virus	Bunyavirales	Peribunyaviridae	Orthobunyavirus	Humans, white tailed deer	Mosquitoes
La Crosse virus	Bunyavirales	Peribunyaviridae	Orthobunyavirus	Humans, chipmunks, squirrels	Ochlerotatus triseriatus mosquitoes
Oropouche fever virus	Bunyavirales	Peribunyaviridae	Orthobunyavirus	Humans, primates, sloth, marsupials, birds	Aedes serratus and Culex quinquefasciatus Mosquitoes, midges
Heartland virus	Bunyavirales	Phenuiviridae	Bandavirus	Humans, white tailed deer raccoons	Amblyomma americanum ticks
Rift Valley fever virus	Bunyavirales	Phenuiviridae	Phlebovirus	Humans, ovine, goat, sheep ruminants	Culex tritaeniorhynchus and Aedes vexans mosquitoes
Sandfly fever virus	Bunyavirales	Phenuiviridae	Phlebovirus	Humans	Psychodidae sandflies
Toscana virus	Bunyavirales	Phenuiviridae	Phlebovirus	Humans, dogs, goats	Phlebotomus sandflies
Barmah forest fever virus	Martellivirales	Togaviridae	Alphavirus	Humans, marsupials	Aedes vigilax and Culex annulirostris mosquitoes
Chikungunya	Martellivirales	Togaviridae	Alphavirus	Humans, primates	Aedes albopictus, Aedes aegypti mosquitoes
Eastern equine encephalitis virus	Martellivirales	Togaviridae	Alphavirus	Humans, birds	Culiseta melanura and Cs. morsitans mosquitoes
Mayaro fever virus	Martellivirales	Togaviridae	Alphavirus	Humans, primates	Haemagogus mosquitoes
O'nyong -nyong	Martellivirales	Togaviridae	Alphavirus	Humans	Anopheles mosquitoes
Ross River virus	Martellivirales	Togaviridae	Alphavirus	Humans, macropods	Ochlerotatus vigilax and Culex mosquitoes
Sindbis disease virus	Martellivirales	Togaviridae	Alphavirus	Humans, passerine birds	Aedes, Culex and Culiseta mosquitoes
Venezuelan equine encephalitis virus	Martellivirales	Togaviridae	Alphavirus	Humans, horses, donkeys, zebras	Aedes albopictus and Culex mosquitoes
Western equine encephalitis virus	Martellivirales	Togaviridae	Alphavirus	Humans, birds	Culex tarsalis mosquitoes
Bovine ephemeral fever virus	Mononegavirales	Rhabdoviridae	Ephemerovirus	Bovine	Culicoides oxystoma and nipponensis biting midges
Vesicular stomatitis virus	Mononegavirales	Rhabdoviridae	Vesiculovirus	Humans, bovine, swine, equine	Culicoides midges, sandflies, blackflies
African horse sickness virus	Reovirales	Reoviridae Sedoreovirinae	Orbivirus	Horses, donkeys, mules, zebras	Culicoides imicola midges
Banna virus	Reovirales	Reoviridae Sedoreovirinae	Seadornavirus	Humans, pigs, cattle	Culex, Aedes and Anopheles mosquitoes
Bluetongue virus	Reovirales	Reoviridae Sedoreovirinae	Orbivirus	Goats, cattle, wild ruminants	Culicoides imicola and Culicoides variipennis midges
Colorado tick fever virus	Reovirales	Reoviridae Spinareovirinae	Coltivirus	Rodents, ground squirrels	Dermacentor ticks
Equine encephalosis virus	Reovirales	Reoviridae Sedoreovirinae	Orbivirus	Horses, donkeys, zebras	Culicoides midges

Table 4 Viruses of invertebrate vectors of plant viruses (The Order is given in brackets below the family name. The number of species in the genus is given by the number in brackets after the genus name)

Family	Genus (type species)	Genome type and size	Morphology	Invertebrate vector (transmission type)
<i>Betaflexiviridae</i> (Quinvirinae) (Tymovirales)	<i>Carlavirus</i> , Carnation latent virus (53)	+ v ssRNA, 5.8 to 9 kb	Helical, 12 to 13 × 470 to 1,000 nm	Aphid and whitefly (non-circulative, semi-persistent)
<i>Bromoviridae</i> (Martellivirales)	<i>Alfavirus</i> , Alfalfa mosaic virus (1) <i>Cucumovirus</i> , Cucumber mosaic virus (4)	+ ve ssRNA, tripartite Alfa- 2.1 to 2.2/2.6 Cucumo- 3.0/3.2 to 3.4 kb	Alfa-bacilliform 18 × 30 to 57 nm Cucumo- icosahedral T=3, 26 to 35 nm diameter	Aphid (non-circulative, nonpersistent)
<i>Caulimoviridae</i> (Ortervirales)	<i>Caulimovirus</i> , Cauliflower mosaic virus (13) <i>Cavenovirus</i> , Cassava vein mosaic virus (2) <i>Roseadnavirus</i> , Rose yellow vein virus (1) <i>Soymovirus</i> , Soybean chlorotic mottle virus (4) <i>Tungovirus</i> , Rice tungro bacilliform virus (1)	dsDNA, open circular, 7.0 to 8.2 kb	Icosahedra T=7, 45 to 50 nm diameter or bacilliform (Tungovirus) 30 nm × 60 to 900	Aphid, mealybug, leafhopper (non-circulative, semi-persistent)
<i>Closteroviridae</i> (Martellivirales)	<i>Ampelovirus</i> , Grapevine leafroll-associated virus 3 (12) <i>Closterovirus</i> , Beet yellows virus (16) <i>Crinivirus</i> , Lettuce infectious yellows virus (14)	+ ve ssRNA Ampelo- and Closterovirus- monopartite, 15.5 to 19.3 kb Crini-bisegmented 7.8 and 9.1 kb	Ampelo- and Closterovirus- single flexuous helix, 3.4 to 3.8 × 650 to 2,200 nm Criniviruses, bipartite helices, 10 to 13 × 650 to 85/10 to 13 × 700 to 900	Aphid, whitefly, softscale mealybug (non-circulative, semi-persistent)
<i>Fimoviridae</i> (Bunyavirales)	<i>Emaravirus</i> , European mountain ash ringspot-associated emaravirus (11)	– ve ssRNA, quatrpartite, 1.3/1.6/2.0/6.9 kb	Spherical 80 to 90 nm, enveloped	Eriophyd Mite (?)
<i>Geminiviridae</i> (Gepfuvirales)	<i>Begomovirus</i> , Bean golden yellow mosaic virus (424)	+ ve ssDNA, bipartite, 2.5/2.6 kb	Twined icosahedra T=1, 22 × 38 nm	Whitefly, leaf hopper, aphid, tree hopper (circulative, non-propagative, persistent)
<i>Luteoviridae</i> (Tolivirales)	<i>Enamovirus</i> , Pea enation mosaic virus 1 (5) <i>Luteovirus</i> , Barley yellow dwarf virus (13) <i>Polerovirus</i> , Potato Leafroll virus (26)	+ ve ssRNA, monopartite, 5.3 to 5.7 kb	Icosahedral T=3, 23 to 30 nm diameter	Aphid (circulative, nonpropagative, persistent)
<i>Nanoviridae</i> (Mulpavirales)	<i>Babuvirus</i> , Banana bunchy top virus (3) <i>Nanovirus</i> , Subterranean clover stunt virus (8)	+ ve ssDNA, multipartite, 6 to 8 segments, 1 kb each	Icosahedra T=1, 18 to 19 nm diameter	Aphid, planthopper (circulative, nonpropagative, persistent)
<i>Phenuiviridae</i> (Bunyavirales)	<i>Tenuivirus</i> , Rice stripe tenuivirus (8)	– ve and ambisense ssRNA, 4 to 5 segments	4 to 5 helical circular helices 3 to 10 nm diameter	Planthopper (circulative, propagative, persistent)
<i>Potyviridae</i> (Patatavirales)	<i>Macluravirus</i> , Maclura mosaic virus (10) <i>Potyvirus</i> , Brugmansia mosaic virus (183) <i>Tritimovirus</i> , Wheat streak mosaic virus (6) <i>Rymovirus</i> , Ryegrass mosaic virus (3) <i>Phytoreovirus</i> , Wound tumor virus (3)	+ v ssRNA, 8.0 to 12 kb	Flexuous, helix, 12 to 15 nm × 650 to 850 nm	Aphid, mite, whitefly (non-circulative, nonpersistent)
<i>Reoviridae</i> (Reovirales)		dsRNA, 12 segments, 1.1 to 4.4 kb	Icosahedral, double shell T=2/T=13, 70 nm diameter	Leafhopper (circulative, propagative, persistent)
<i>Rhabdoviridae</i> (Mononegavirales)	<i>Cytorhabdovirus</i> , Lettuce necrotic yellows cytorhabdovirus (23) <i>Alphanucleorhabdovirus</i> , Potato yellow dwarf alphanucleorhabdovirus (9)	– ve ssRNA 12.0 to 14.5 kb	Bullet to bacilliform shape, 45 to 100 nm × 130 to 350 nm, enveloped	Aphid, leafhopper, planthopper (circulative, propagative, persistent)
<i>Secoviridae</i> (Picornavirales)	<i>Nepovirus</i> , Tobacco ringspot virus (40) <i>Fabavirus</i> , Broad bean wilt virus 1 (7) <i>Sequivirus</i> , Parsnip yellow fleck virus (3)	+ ve ssRNA Nepo- bipartite, 3.9/7.5 kb Faba-bipartite, 1.58/3.4 kb Sequi-monopartite, 9 kb	Icosahedral, naked, pseudo T=3, Nepo- 28 to 30 nm diameter, Faba- 28 to 38 nm diameter Sequi- 25 to 30 nm diameter	Nepo- nematode, mite, thrip Faba- aphid, beetle, leafhopper (non-circulative) Sequi- aphid, leafhopper (circulative, propagative)
<i>Tospoviridae</i> (Bunyavirales)	<i>Orthospovirus</i> , Tomato spotted wilt orthospovirus (26)	– ve ssRNA, tripartite, 3, 4, 8, 8.k kb	Spherical enveloped, 80 to 120 nm diameter, 3 RNPs	Thrip (circulative, propagative)
<i>Virgaviridae</i> (Martellivirales)	<i>Tobravirus</i> , Tobacco rattle virus (3)	+ ve ssRNA, bipartite, 4.5/6.8 kb	Helical 22 × 180 to 215; 22 × 46 to 115	Nematodes

Arboviruses in Their Invertebrate Vectors

Only superficially, if at all, covered in this article are viruses that are arboviruses involved in transmitting arboviral disease, like yellow fever, Dengue, Zika even though part of the life cycle involves replication in the insect vectors. Nevertheless summary Table 2 provides a summary of the families of arboviruses and their insect vectors and summary Table 3 is for some better known arboviruses, their taxonomy and vector species. The reader is referred to other chapters in this Encyclopedia which are devoted to more detailed coverage of these viruses.

Plant Viruses in Their Invertebrate Vectors

While many plant viruses are vectored by invertebrates (Table 4), they are not further discussed here but the reader is referred to the corresponding chapters on plant viruses. In terms of the nature of transmission of plant viruses, these can be defined as circulative (virus enters the insect body and circulates, usually through the hemolymph, prior to transmission), non circulative (virus does not enter the insect body but is transmitted physically through contaminated stylet or foregut of the insect) propagative (virus enters the insect and replicates in the insect prior to transmission, usually through the salivary glands) and non propagative (virus enters the insect, usually transported to salivary glands, but does not replicate in it prior to transmission). Transmission of plant viruses can also be defined as persistent, in which the virus is taken up by the insect following circulative means and invade the salivary gland, semi-persistent in which viruses are internalized and retained in the insect foregut, but do not enter the tissues and non persistent in which viruses are retained on the distal tip of the stylet only until it is released during feeding. A summary of some of these invertebrate-vector transmitted plant viruses is provided in Table 4.

Retrotransposons Associated With Invertebrates

Three virus families associated with invertebrates, all in order *Ortervirales* (for reverse transcribing viruses), are actually transposons. While isolated mostly from plants, retrotransposons from these three families were also found to be associated with invertebrates. Retrotransposons in family *Pseudoviridae* [ICTV 1998] genus *Hemivirus* [ICTV 1998], type species *Drosophila melanogaster copia virus* are associated with *Drosophila* and mosquitoes. Retrotransposons in family *Balpaoviridae* [ICTV 2017] with genus *Semotivirus* [ICTV 2017], type species *Ascaris lubricoides virus* are associated with roundworm, lepidoptera and *Drosophila*. Retrotransposons in family *Metaviridae*, [ICTV 1998] genus *Errantivirus*, [ICTV 1998], type species *Drosophila melanogaster Gypsy virus* and genus *Metavirus* [ICTV 1998], type species *Saccharomyces cerevisiae Ty3 virus* have retrotransposons associated with *Drosophila*, *Trichoplusia ni* and *Bombyx mori*. The genome of the erantivirus *Trichoplusia ni* TED virus is 7,510 bp.

Acknowledgments

Much of the information for this summary was gleaned from preprints of the articles on Invertebrate Viruses prepared for this Encyclopedia of Virology 4th edition. I acknowledge the contributions of these authors for being able to use their information. I leaned heavily on the ICTV web sites for the wealth of knowledge provided on up to date taxonomy (some of which changed as I was writing this article), summary articles on different taxa in the 10th report of "The ICTV Report on Virus Classification and Taxon Nomenclature" and the numerous "proposals" that accompany the "history" provided through the taxonomy site.

The articles in the main body of this volume do not cover all the families of viruses infecting invertebrates covered in this summary. In part that is because often not much is known, or in some instances only sequence data is available.

I hope the reader will find the summary Tables (Tables 1–4) of use, as the tables attempt to collate the wealth of the diversity of invertebrate viruses and their taxa. I have made every effort for accuracy, but considering the breadth of information, it is easy to overlook some important information or err on transcription (the writing kind). For these I apologize.

Glossary

Apoptosis Genetically programmed cell death.

Apoptotic bodies Cell vesicles resulting from apoptosis.

Caspase Protease that activates a major portion of programmed cell death.

Endoparasitic wasps Species of insect parasites belonging to the order Hymenoptera, which lay their eggs in insects where the wasp larvae develop.

Per os infection Infection by feeding.

Programmed cell death Genetically programmed cascade proteases and nucleases that cleave DNA and proteins within a cell leading to its death.

Reniform Shaped like a kidney.

Transovarial transmission Transmission of virus inside the egg.

Virion-containing vesicles Vesicles containing virions formed by ascoviruses by rescue of apoptotic bodies induced by ascovirus infection.

Introduction

The family *Ascoviridae* is one of the newest families of viruses, established in 2000 to accommodate several species of a newly recognized type of DNA virus that attacks larvae of insects of the order Lepidoptera. It consists of two genera, *Ascovirus* and *Toursvirus*; for practicality, here we refer to the collective members of the family *Ascoviridae* as ascoviruses. Viruses of this family produce large, enveloped virions, measuring 130 nm in diameter by 300–400 nm in length, and when viewed by electron microscopy have a reticulated surface appearance. They are typically bacilliform or reniform in shape, and contain a circular double-stranded DNA genome that, depending on the species, ranges from 119 to 200 kbp. Whereas the virions of ascoviruses are structurally complex like those of other large DNA viruses that attack insects, such as those of iridoviruses (family *Iridoviridae*) and entomopoxviruses (family *Poxviridae*), they differ from these in two significant aspects. First, ascoviruses are transmitted from diseased to healthy lepidopteran larvae or pupae by female endoparasitic wasps when these lay eggs in their hosts. Second, ascoviruses have a unique cell biology and cytopathology in which shortly after infecting a cell, they induce apoptosis and then rescue the developing apoptotic bodies and convert these into virion-containing vesicles. This aspect of viral reproduction apparently evolved to disseminate virions to the larval hemolymph (blood) where they could contaminate the ovipositors of female wasps so that the virus could be transmitted to new hosts. Ascoviruses appear to occur worldwide, wherever there are endoparasitic wasps and larvae of species belonging to the lepidopteran family Noctuidae. However, as these viruses have been discovered relatively recently and their signs of disease are not commonly known in the scientific community, relatively few ascovirus species have been described.

History

The first ascoviruses were discovered during the late 1970s in southern California where they were found causing disease in larvae of moths belonging to the lepidopteran family Noctuidae. Diseased larvae were recognized by the presence of hemolymph that was very white and opaque, in marked contrast to the hemolymph of healthy larvae which is translucent and slightly green (Fig. 1). The color and opacity of the hemolymph in diseased larvae was shown to be due to the presence of high concentrations of vesicles that contained virions (Fig. 2). The white hemolymph and virion-containing vesicles are diagnostic for the disease, and the name for this group, ascoviruses (derived from the Greek *asco* meaning “sac”), was chosen on the basis of the latter characteristic. Since the discovery of the first ascovirus, ascoviruses have been isolated as the cause of disease in many species of noctuid larvae. In addition, an ascovirus that attacks the pupal stage of a species belonging to the family Yponomeutidae was discovered in the 1990s in France.

Distribution and Taxonomy

With respect to distribution, ascoviruses have been reported from the United States, Europe, Australia, and Indonesia, and it is highly probable that they occur worldwide. This is because their most common hosts, larvae of lepidopteran species belonging to

Fig. 1 Major characteristics of the disease typically caused by ascoviruses in lepidopteran larvae. (A) and (B) Healthy and ascovirus-infected larvae, respectively, of the cabbage looper, *Trichoplusia ni*, infected with *Trichoplusia ni* ascovirus. Note the opaque white hemolymph in the infected larva. (C) Spot plate containing hemolymph from healthy (left) and infected larvae (right). (D, E) Sections through lobes of fat body from a healthy and infected larva, respectively, of the fall armyworm, *Spodoptera frugiperda*, infected with *Spodoptera frugiperda* ascovirus. Note the greatly hypertrophied cells in the fat body of the infected larva. The cells in most of this tissue have already cleaved into viral vesicles. N, nuclei.

the family Noctuidae, the largest family of the order Lepidoptera, as well as their most common vectors, endoparasitic wasps of the families Braconidae and Ichneumonidae, are distributed throughout the world. Although only a few ascovirus species have been described to date, there are probably many, including variants, that occur worldwide. Thus, given the common occurrence of their hosts and vectors, it is possible that ascoviruses are very common insect viruses. That they have not been discovered in large numbers, for example like baculoviruses (family *Baculoviridae*), is probably because they cause a chronic disease with few easily detectable signs, making it difficult for individuals not familiar with the disease to recognize diseased larvae in field populations.

At present, five species of ascoviruses are officially recognized based on a combination of properties including the relatedness of 28 key genes coding among others for the DNA polymerase and major capsid protein, the percent identity between their sequenced genomes, their lepidopteran host range, and their tissue tropism (Table 1). They are split into two genera, *Ascovirus* and *Toursvirus*. The type species of the *Ascovirus* genus is *Spodoptera frugiperda* ascovirus 1a (SfAV-1a), with the other species being *Trichoplusia ni* ascovirus 2a (TnAV-2a) and *Heliothis virescens* ascovirus 3a (HvAV-3a). To date, the *Toursvirus* genus contains only one virus species originally called *Diadromus pulchellus* ascovirus 4a (DpAV-4a), and now named *Diadromus pulchellus* *toursvirus* (DpTV-4a). The Arabic numeral reflects the order in which each species was formally recognized, whereas the lower case letter indicates variants of the type species. Variants from the type species are recognized by different consecutive lower case numbers; for example, TnAV-2b and 2c would represent two different variants of TnAV-2a recognized subsequently. Herein, these viruses are referred to by their acronyms without the numerical and lower case suffix.

Members of the *Ascovirus* genus have been isolated from many more insect species than those listed above, but these isolates have turned out to be variants of known ascoviruses, and therefore they have not been named after the host from which they have been isolated. For example, ascoviruses related to TnAV and HvAV have been isolated from noctuid species such as *Autographa precationis*, *Helicoverpa zea*, *Helicoverpa armigera*, and *Helicoverpa punctigera*; however, they do not bear the name of their host of isolation. What this implies is that ascoviruses belonging to the TnAV and HvAV species have a broad and overlapping host range among different noctuid species, although this has only been tested experimentally to a limited extent.

Virion Structure and Composition

Depending on the species, the virions of ascoviruses are either bacilliform or reniform in shape, with complex symmetry, and very large, measuring about 130 nm in diameter by 300–400 nm in length. Although variations occur in the virion structure among various ascovirus species, their structural components appear to be essentially the same. Ascovirus virions consist of an inner particle surrounded by an outer envelope (Fig. 2). The inner particle is complex containing a DNA/protein core as well as an apparent internal lipid bilayer surrounded by a distinctive layer of protein subunits. Thus, the virion appears to contain two lipid membranes: one associated with the inner particle and the other forming the lipid component of the envelope. In negatively stained preparations, virions have a distinctive reticulate appearance, which is thought to be due to superimposition of subunits on the surface of the internal particle with those in the envelope.

Fig. 2 Structural and morphological characteristics of ascovirus virions and virion-containing vesicles. (A) Wet mount preparation viewed with phase microscopy of hemolymph from a *Spodoptera frugiperda* larva infected with *Spodoptera frugiperda* ascovirus (SfAV). The spherical refractile bodies are virion-containing vesicles. (B, C) Electron micrographs of ultrathin sections through viral vesicles produced by *Trichoplusia ni* ascovirus (TnAV) and SfAV, respectively. (D) Matrix of the occlusion body produced by SfAV. The occlusion consists of virions, protein, and small spherical vesicles. (E, F) Negatively stained virions of SfAV and TnAV, respectively. Note the reticulate appearance of the virions. (G, H) Electron micrographs of ultrathin cross sections through inner particles of SfAV after formation (G) and during envelopment (H). (I) Ultrathin cross section through a fully developed virion of TnAV.

As indicated by the size and complexity of the virions, the genome of ascoviruses is large, and consists of a single molecule of double-stranded circular DNA. The genomes of SfAV, TnAV, HvAV, or variants of these, in the genus *Ascovirus*, and DpTV-4a the sole virus in the genus *Toursvirus* have been sequenced (Table 1). The SfAV-1a genome is 157 kbp and codes for at least 120 proteins, whereas the TnAV genomes are slightly larger, 174–186 kbp, and code for at least 165–178 proteins. The genomes of HvAV variants range from 186 to 200 kbp and code for approximately 180–190 potential proteins. The DpTV-4a genome is 119 kb in size and encodes about 119 proteins. Based on gel analyzes, ascovirus virions contain more than 12 structural polypeptides ranging in size from 12 to 200 kDa. Furthermore, proteomic analysis revealed that SfAV-1a virion is composed of at least 21 proteins, whereas similar analyzes identified at least 67 proteins in the virion of HvAV-3i. The marked difference in the virion protein profiles of SfAV-1a and HvAV-3i could be due to inadvertent contamination with non-structural proteins or a higher level of structural complexity in the HvAV-3i virion. Regardless, the two major virion proteins in ascovirus virions are, invariably, the major capsid protein and members of an unusual large cationic protein family (ascovirus P64 homologs) that functions in

condensing and encapsidating ascovirus genomic DNA. In addition to proteins and the DNA genome, the presence of an envelope as detected by electron microscopy, as well as experiments with detergents and organic solvents, indicate that virions contain a substantial lipid component. And, as in other enveloped viruses of eukaryotes, it is likely that the virion also contains carbohydrate in the form of glycoproteins, though at present none have been identified.

Transmission and Ecology

One of the most interesting features of ascoviruses is that their transmission from host to host appears to be dependent on their being vectored by female endoparasitic wasps (order Hymenoptera). Ascoviruses are extremely difficult to transmit *per os*, with typical infection rates averaging less than 15% even when larvae are fed as many as 10^5 virion-containing vesicles in a single dose. In contrast to this, infection rates for caterpillars injected with as few as 10 virion-containing vesicles are typically greater than 90%. Moreover, experiments with parasitic wasps show that they can effectively transmit ascoviruses to their noctuid hosts. For example, when females are allowed to lay eggs in ascovirus-infected noctuid caterpillars, thereby contaminating their ovipositor, and then allowed to lay eggs in healthy larvae, the majority of the latter contract ascovirus disease. Interestingly, though the parasitoid eggs hatch in their infected noctuid hosts, the parasitoid larvae die as the ascovirus disease develops in the caterpillar. Under field conditions, the prevalence of ascovirus disease in caterpillars is correlated with rates of parasitization by endoparasitic wasps. When wasps from these populations are collected in the field and allowed to oviposit in healthy caterpillars reared in the laboratory, the latter often exhibit ascovirus disease within a few days. Thus, laboratory and field studies provide sound evidence that the primary mechanism for the transmission of ascoviruses attacking noctuid larvae is through being vectored mechanically by parasitic wasps. No evidence has been found in the lepidopteran hosts for transovum or transovarial transmission.

In the case of DpTV (genus *Toursvirus*), the association of the virus with its wasp and caterpillar hosts is much more intimate. DpTV DNA is carried in wasp nuclei as a circular molecule, and small numbers of virions are produced in the oviducts of females. However, the virus does not cause noticeable pathology in the wasp host. The females lay eggs in the pupal stage of the lepidopteran host, *Acrolepiopsis assectella*, introducing small numbers of toursvirus virions along with the wasp eggs. These virions invade lepidopteran host cells, replicate, and initiate destruction of major host tissues. The wasp larva then emerges from the egg and feeds on the host tissues and toursvirus virions. The DpTV genome is carried extrachromosomally by both male and female wasps, where it is apparently transmitted from generation to generation transovarially. These observations make ascoviruses the only known group of viruses pathogenic to insects that are primarily dependent on vectors for their transmission.

Now that the characteristics of the disease are known, field studies in the southeastern United States and California are beginning to show that ascoviruses are probably the most common type of virus to occur during most of the year in populations of several important noctuid pests, including the cabbage looper, *Trichoplusia ni*, fall armyworm, *Spodoptera frugiperda*, and the corn

Fig. 3 Major stages of cellular pathogenesis caused by a typical ascovirus, a process that resembles apoptosis. After infection, the nucleus enlarges and the nuclear membrane invaginates, and then lyses. Subsequently, the plasmalemma of the cell invaginates and coalesces with cytoplasmic membranes, apparently formed *de novo*, thereby dividing the cell into a cluster of virion-containing vesicles. These vesicles dissociate and are liberated into the hemolymph as the basement membrane of infected tissues degenerates. Virion assembly becomes apparent as the nuclear membrane lyses, and continues throughout all subsequent stages of vesicle formation.

earworm, *Helicoverpa zea*. Prevalence rates range from 10% to 25%, depending on the species and time of the year, with the highest rates of infection, as noted above, being correlated with high levels of parasitization. In South Carolina, ascovirus infection rates as high as 60% have been reported in populations of noctuid larvae at the end of summer.

Host Range

The experimental host range of ascoviruses varies with the viral species. TnAV, HvAV, and SeAV have a broad host range and are capable of replication in a variety of noctuid species, as well as in selected species belonging to other families of the order Lepidoptera. Alternatively, the experimental host range of SfAV is limited to other species of the genus *Spodoptera*. DpTV can replicate in hymenopteran and lepidopteran hosts closely related to its natural host species, *A. assectella*. To propagate virus in the laboratory, all ascoviruses can be grown in their larval or pupal hosts. To infect caterpillars, they are injected with virus in the third, fourth, or early fifth instar, and virion-containing vesicles are harvested from the hemolymph 5–7 days later. While ascoviruses can be propagated in lepidopteran host cell lines, virus pathology usually is not as distinct as that of *in vivo*. In addition, virus replication *in vitro* does not appear to be as high as that *in vivo*.

Pathology and Pathogenesis

Signs of Disease

In both natural and laboratory environments, the initial signs of ascovirus disease are very subtle, and this probably accounts for why ascoviruses were discovered only recently. The most obvious sign of disease within 24 h of infection is a decrease in the normal rate of feeding. The feeding rate continues to slow as the disease progresses, and as a result larvae fail to gain weight or advance in development. Healthy larvae, particularly in the early stages of development, will easily quadruple their weight and size in a period of 3 or 4 days, whereas ascovirus-infected larvae cease to grow and may actually lose weight. This feature of ascovirus disease is almost impossible to detect in infected larvae in the field. However, it is easily noticed under laboratory conditions when infected and healthy larvae are reared side by side over a period of a few days. A second feature easily noted in the laboratory is that ascovirus diseases are chronic, though usually fatal. When infected during early stages of development, ascovirus-diseased larvae often survive for 2 or 3 weeks beyond the time at which most healthy larvae have completed their development and pupated. Signs of disease other than these are minor, but include the inability to completely cast the molted cuticle, a bloated thoracic region, and a white or creamy discoloration and hypertrophied appearance of the larval body at advanced stages of disease development.

Cytopathology and Cell Biology

In comparison to all other known viruses, the most unique property of ascoviruses is the unusual cytopathology that leads to the formation of the virion-containing vesicles. This process resembles apoptosis, and previous studies of the SfAV-1a genome have shown that it encodes a functional executioner caspase, synthesized 9 h after infection, which by itself is capable of inducing apoptosis (Fig. 3); at present, no other virus is known to encode a functional caspase. Although *in vitro* studies have demonstrated that knock-down of SfAV-1a caspase by RNA interference significantly reduced the formation of apoptotic vesicles, it is unclear whether caspase homologs in other ascoviruses participate in this process. For example, in a similar study a caspase-like gene in HvAV-3e was shown not to be implicated in apoptosis but was essential for virus replication.

At the cellular level *in vivo*, the disease begins with extraordinary hypertrophy of the nucleus accompanied by invagination of sections of the nuclear envelope, followed by a corresponding enlargement of the cell. Cells typically grow from 5 to 10 times the diameter of uninfected cells. As the nucleus enlarges, the nuclear envelope ruptures and disintegrates into fragments. At about this stage, the cell plasmalemma begins to invaginate along “planes” toward the now anucleate cell center. Concomitantly, sheets of membrane form closely adjacent to mitochondria that accumulate along the planes. As this process continues, the membrane sheets coalesce and join the invaginating plasmalemma, thereby cleaving the cell into a cluster of 20 to more than 30 vesicles, ranging in size from 5 to 10 μm in diameter. This aspect of ascovirus cellular pathology resembles the formation of apoptotic bodies during apoptosis. However, rather than dissipate as the cell dies, the developing apoptotic bodies are rescued by the virus and progress to form vesicles in which virions continue to assemble. These virion-containing vesicles, also referred to as viral vesicles, typically remain in the tissue until the basement membrane ruptures, though on occasion cell hypertrophy can be so great that the enlarging cell erupts out through the basement membrane of the infected tissue, releasing large fragments of the infected cell directly into the hemolymph. Analysis of ascovirus genomes shows that, unlike many other large DNA viruses, ascoviruses encode several lipid-metabolizing enzymes that are likely involved in the process of converting developing apoptotic bodies into virion-containing vesicles. Recent transcriptome analysis have shown that genes coding for a patatin-like phospholipase, a PlsC phosphate acyltransferase, a fatty acid elongase, and an esterase/lipase in SfAV-1a are highly expressed during later stages of virus infection *in vivo*. These enzymes are known to modify fatty acid chain length and the degree of lipid saturation, presumably generating novel lipid components in the virion and/or the membranes of viral vesicles. Regarding the latter, it is possible that these lipids, in part, function in providing stability to viral vesicles as they circulate in hemolymph for an extended period encompassing several days or weeks, and when these vesicles are disseminated through oviposition by female parasitic wasps. Another interesting aspect of this cytopathology is that the mitochondria, apparently under ascovirus control, are reprogrammed to assist synthesis of membranes that cleave the cell into the viral vesicles in which most replication occurs.

Although the process by which viral vesicles are cleaved from cells varies among different ascoviruses, the histopathology is similar among virtually all ascoviruses. Vesicles accumulate in the tissues where they are formed, but as these tissues degenerate during disease progression, the basement membrane of infected tissues deteriorates and ruptures, allowing the vesicles to spill out into the hemolymph. There they accumulate reaching concentrations as high as 10^7 – 10^8 vesicles per ml within 3–4 days of infection. There is some evidence that viral replication proceeds within the vesicles as they circulate in the hemolymph, and thus this tissue must also be considered one of the tissues attacked by ascoviruses. In fact, because such high concentrations of viral vesicles are found in the hemolymph, this tissue could be considered a major site of infection, particularly if it is eventually shown that these viruses continue to replicate in the vesicles as they circulate in the hemolymph.

Despite the chronic nature of the disease caused by ascoviruses, virion-containing vesicles are present in the hemolymph within 2 or 3 days of infection. When the virus replicates in cells *in vitro*, the vesicles are formed within 12–16 h of infection. The rapid development and circulation of the viral vesicles in the hemolymph probably evolved to enhance transmission of the virus by parasitic wasps.

Tissue Tropism

The cytopathology of ascoviruses is consistent among different viral species; however, considerable variation occurs with respect to the tissues attacked, that is, in which replication occurs. TnAV, HvAV, and SeAV exhibit a relatively broad tissue tropism infecting the tracheal matrix, epidermis, fat body, and connective tissue. Differences exist between these species in that some HvAV variants infect the epidermis much more extensively than TnAV variants, whereas some of the latter can also replicate more extensively in fat body cells, but appear only to do this when larvae are infected early in their development. Alternatively, the type species, SfAV, and its variants have a very narrow tissue tropism, with the fat body being the primary site of infection. DpTV occurs in the nuclei of all tissues of its wasp host, but appears to only produce progeny in ovarian tissues. In its lepidopteran pupal host, it attacks and replicates in a wide variety of tissues.

Replication and Virion Assembly

Although there have been few biochemical studies of viral DNA replication or protein synthesis, studies carried out with ascoviruses *in vivo* and *in vitro* show that progeny virions first appear about 12 h after infection. Virion assembly is initiated after the nucleus ruptures, and occurs prior to and during the cleavage of the cell into viral vesicles. The first recognizable structural

component of the virion to form is the multilaminar layer of the inner particle. Based on its ultrastructure, this layer consists of a unit membrane and an exterior layer of protein subunits. As the multilaminar layer assembles, a dense nucleoprotein core aggregates on the interior surface. This process continues until the inner particle is complete. After formation, the inner particle is enveloped by membranes within the cell or vesicle. These membranes are apparently synthesized *de novo*. Thus, the assembly of the virions is reminiscent of that in other viruses with complex virions, such as the iridoviruses, herpesviruses, and poxviruses, where the virions differentiate after association of the precursors of virion structural components.

After formation, the virions of the TnAV ascovirus accumulate toward the periphery of the vesicle where they often form inclusion bodies, that is, aggregations of virions (Fig. 2). In SfAV, occlusion bodies are formed in which the virions are actually occluded in a “foamy” vesicular matrix that consists of a mixture of protein and minute spherical vesicles. When viewed with phase microscopy, these viral inclusion and occlusion bodies are phase bright, and are largely responsible for the highly refractile appearance of the vesicles. Ascoviruses do not typically form the types of occlusion bodies characteristic of other types of DNA insect viruses, such as baculoviruses and entomopoxviruses.

Origin and Evolution

The subject of viral evolution over millions of years has received relatively little study due to the lack of a fossil record. Moreover, viruses are considered polyphyletic, and thus most of the more than 70 families of viruses are thought to have originated independently. In this regard, ascoviruses may provide a unique opportunity to obtain insights into virus evolution over long periods. Phylogenetic comparisons of ascovirus genes sequenced to date including those coding DNA polymerase and major capsid protein as well as 20 other proteins indicate that these viruses evolved from a lepidopteran iridovirus (family Iridoviridae). Iridoviruses, in turn, appear to share a common ancestor with two families of *Megavirales*, *Marseilleviridae* and *Pithoviridae* which attack certain aquatic unicellular organisms.

Future Perspectives

At present, too little is known about ascoviruses to assess whether they are or will turn out to be of economic importance. Their poor infectivity *per os* makes it highly unlikely they will ever be developed as viral insecticides, especially given the successful advent of insect-resistant transgenic crops. However, as more entomologists become familiar with the disease caused by ascoviruses, it may be shown that in habitats rarely treated with chemical insecticides, such as transgenic crops, these viruses are responsible for significant levels of natural pest suppression, particularly where parasitic wasps are abundant. Such findings would encourage even greater emphasis on the development of biological control and other more environmentally sound methods of pest control. With respect to the cell biology of viral vesicle formation, ascoviruses provide an interesting model for how apoptosis can be manipulated at the molecular level. Additionally, study of the unusual process by which ascoviruses rescue the developing apoptotic bodies to form viral vesicles could lead to insights into how cells manipulate the cytoskeleton and mitochondria. Finally, it is possible that viral vesicles will provide a unique anucleate cellular system for studying the replication of a complex type of enveloped DNA virus *in vitro*.

Glossary

Apoptosis A type of programmed cell death important for the normal development of organisms and used as a defense mechanism by cells to prevent the replication of a pathogen and their further propagation. The process is characterized by DNA fragmentation and cell blebbing. Cysteine-aspartases are caspases which cleave proteins after aspartic acids and are the active enzymes that drive the process.

Co-option Existing genes acquiring a different function and/or regulation, resulting from natural selection.

Horizontal gene transfer Lateral transfer of genes between genomes, having a role in evolution and adaptation and differing from vertical gene transfer or the transfer of genes from a parent to an offspring.

Host range Group of host species that are permissive and susceptible to infection by a virus.

Introduction

Viruses are obligate intracellular parasites that depend on cellular metabolism and factors to support their multiplication and propagation between hosts. Viral replication cycles, involving the disassembly and reassembly of viral components to generate new infectious viral particles, provide ample opportunities for viral and host proteins to interact, genome segment exchange and rearrangement, and competition for mutually needed abundant or limited resources used by viruses and hosts. These interactions lead to an arms race between viruses trying to multiply and host cells mounting immune defenses to halt virus multiplication and ameliorate any cytopathic effects. The process leads to co-evolution of viruses and their hosts. Viruses need to carefully choreograph their host defense weaponry, as killing a host too quickly can result in a dead-end host, curtailing desired levels of virus multiplication and spread. There are many known examples of viruses having acquired host genes that benefit their replication and, in some cases, these genes have been co-opted to defeat the host. The horizontal transfer of genes is bidirectional—viruses acquiring genes from a host or another co-infecting pathogen and hosts acquiring viral genes.

This review will provide background on gene acquisition by viruses from a host or other organism within that host. It will also summarize gene acquisition from a virus to a host. The general role and examples of host-captured genes by baculoviruses will be discussed in more detail, focusing on two broad groups, viral host range genes and genes that affect host defense pathways.

Viruses Acquiring Genes From Their Hosts

Viruses may acquire genes from other organisms and these may be maintained in viral genomes if they are beneficial for their replication. Acquired genes may serve to manipulate the immune system of the host, by evading, avoiding or hindering immune factors that curtail their replication. In addition, virus-acquired host genes can enhance virus replication in their native host or expand their host range, further ensuring their successful spread. Captured genes typically evolve faster than the cellular counterpart, often making the lineage of acquired genes hard to determine and study. In some cases, specific genes have been acquired independently multiple times, for example, IL-10 in herpesviruses and poxviruses. Viruses may acquire genes from their host, a co-infecting pathogen (*e.g.*, virus or bacteria) or the microbiome of the host ([Fig. 1](#)). The transfer of DNA may be complex involving three or more pathogen-host interactions. For example, bacterial viruses that along with their obligate intracellular bacterial host co-infect a eukaryotic organism may facilitate DNA exchange between these organisms. Bacteriophage WO from *Wolbachia*, Gram-negative bacteria that infect several arthropods, carries a eukaryotic association module, a segment of DNA in the bacterial virus with potentially functional eukaryotic gene domains (*e.g.*, spider toxic, protease cleavage sites), indicating the lateral transfer of genes and the potential role of these domains in factor mimicry.

Hosts Acquiring Genes From Infecting Viruses

Although it is more widely discussed how viruses capture genes from their hosts to supplement their replication advantages, the reciprocal also occurs, namely, host organisms acquiring genes from the viruses that infect them. As with virus co-opted genes, hosts can use viral genes for specific purposes and the function of the gene product may be modified. Viruses can integrate into host genomes and may remain as part of the host genome indefinitely. Acquired genes may be co-opted and function as antiviral defense genes, lending a twist to the arms race between viruses and their hosts, where the virus or its host acquired a gene from its

Fig. 1 *Gene flow to viruses.* Movement of genes to viruses from the host organism, co-infecting pathogens or organisms in the microbiome of the host. Reciprocal movements may also take place.

foe to defeat it. Analyses have indicated that viral RNA-dependent RNA polymerase and capsid genes, two viral-specific genes, have been found nested in cellular genomes and, in some cases, expressed, but their specific function in the host genome remains to be determined. Horizontal gene transfer of genes may also occur in non-viral invaders; for example, the pillbug *Armadillidium vulgare* was recently shown to have acquired a gene from the bacteria *Wolbachia*. Gene transfer can also occur by the integration of virus genes into a host genome, where viral genes usually evolve at the pace of host genes. Some viruses use integration of their genome into host genomes as part of their replication strategy, while others may integrate depending on the environment or to hide from host defense pressures. There is ample evidence of viral genomes “fossilized” in host genomes, underscoring the long relationship and co-evolution between viruses and hosts.

A startling example of virus evolution is exemplified by polydnaviruses. Polydnaviruses have symbiotic relationships with two large groups of parasitic wasps, ichneumonid and braconid wasps, that are evolutionarily different. The wasps parasitize lepidoptera larvae as they oviposition. During oviposition, the eggs are injected along with polydnavirus particles. The encapsidated genomes of polydnaviruses encode genes that interfere with lepidopeteran larvae immunity and physiology, allowing egg development. In turn, polydnaviruses require the wasp host to spread the virus, since the viral genes that encode structural and replication proteins are encoded in the wasp genome and are not in the encapsidated polydnavirus genome. The ovaries of braconid wasps were reported to express 29 genes with homologs in nudiviruses and derived from nudiviruses (viruses evolutionarily closely related to baculoviruses). A significant number of these 29 genes (62% or 18 genes) are also baculovirus core gene homologs, as well as being in nudiviruses. Baculovirus core genes are carried by all baculoviruses sequenced to date and are essential for baculovirus replication. Thus, it appears that polydnaviruses evolved from the integration of nudiviruses into the genomes of wasps, aiding wasp reproduction success and expanding the gene repertoire of wasps to more effectively parasitize hosts.

Baculovirus Replication

Baculoviruses belong to the family *Baculoviridae* and the prototype baculovirus is *Autographa californica* multicapsid nucleopolyhedrovirus (AcMNPV). Baculoviruses naturally infect insects, yet baculovirus virions can enter—but cannot replicate in—many other types of animal cells. The majority of baculoviruses discovered to date infect the larval stage of insects in the order Lepidoptera, which comprises moths and butterflies. A few other baculoviruses, considered more ancient, infect insects in the orders Diptera (mosquitoes) and Hymenoptera (sawflies). Baculoviruses carry a double-stranded circular DNA genome, ranging in length from 80- to 180-kilobasepairs that is contained in an enveloped rod-shaped nucleocapsid. Baculovirus genes are transcribed from both DNA strands with short intergenic regions, and their genomes can be engineered to incorporate large segments of foreign DNA.

During prototypical baculovirus replication, two types of infectious virions are produced, budded and occlusion-derived virions. Both virion types are produced in the nucleus of infected cells and have identical genomes and capsids, but different envelopes, envelope proteins, and virion morphology. The composition of their envelopes and an environmentally-stable protein matrix surrounding the occlusion-derived virions are essential to carry out distinct functions in the replication cycle of the virus. The budded virus exits the nucleus and buds through the cell plasma membrane at late times post infection, obtaining the viral-encoded fusion protein necessary for entry into new cells. Thus, the budded virus is responsible for spreading infection between cells and is the form of the virus used in cell culture. The occlusion-derived virus is produced at very late times post infection. In some baculoviruses, multiple nucleocapsids (MNPVs) are co-enveloped and then occluded in a protein matrix composed of the protein polyhedrin. In single NPVs (SNPVs), single nucleocapsids are enveloped and embedded in polyhedra. Polyhedra are protein crystals containing virions that form an occlusion body. Polyhedrin protects virions in the environment once virions are released from an infected host, allowing transmission of the virus to other hosts. Additional information on the replication of baculoviruses is described in other articles in this volume.

Fig. 2 *Baculovirus* genes with homology to genes in other organisms. Baculoviruses have acquired genes that fulfill several purposes. Proposed origin of genes or homologies to cellular genes is indicated in parentheses. Information was obtained mainly from Hughes, A.L., Friedman, R., 2003. Genome-wide survey for genes horizontally transferred from cellular organisms to baculoviruses. *Molecular Biology and Evolution* 20, 979–987. Thèzè, J., Takatsuka, J., Nakai, M., Arif, B., Herniou, E.A., 2015. Gene acquisition convergence between entomopoxviruses and baculoviruses. *Viruses* 7, 1960–1974.

Baculovirus Acquisition of Genes

At least 25% of baculovirus proteins have been shown to directly interact with host factors. The lineages of many of these interacting viral factors can be traced to cellular counterparts, indicating horizontal gene transfer taking place in different baculoviruses at different times in evolution and interactions on an evolutionary scale. A systematic study of virus-host interacting proteins using published work revealed that 29 viral proteins had been shown to interact with cellular host factors or pathways.

The study of an overlapping host repertoire between two insect viruses, entomopoxviruses and baculoviruses, suggested analogous selection pressures from their respective host, and this may have led to similar genetic acquisitions and repurposing of genes to ensure virus replication. Phylogenetic analyses using these acquired genes indicated that genes had been transferred to insect viruses following coinfections of insects with viruses and other organisms. The gene origin of several virus-acquired genes was traced to genes obtained from bacteria, and multicellular or unicellular eukaryotes (Fig. 2). In some cases, acquired genes could be traced to the host order, Lepidoptera, and there was clear indication that horizontal gene transfer may have taken place. The authors also cited examples of viral genes that seem to have no cellular corresponding homolog and are only carried by a virus (es). Since some of these genes are conserved in both virus families, it implied that acquired genes conferred a fitness to the virus, retaining these genes.

In addition to gene acquisition from the host and co-option of genes, many baculovirus genes are under positive selection, and this serves to avoid the immune system of the host or other pressures. Genes under positive selection include viral genes involved in DNA replication (e.g., *helicase*), structural genes (e.g., *ODV-e66*), transcription genes (e.g., *lef-4*), apoptosis inhibitor genes (e.g., *p35*) and others, painting a complete picture of adaptation that ensure fitness. Some of these genes have homologies to host genes (e.g., *helicase*) and others do not (e.g., *p35*).

A total of 15 proteins or 11% of proteins from the *Bombyx mori* NPV had recognizable counterparts in the host *Bombyx mori* and a number of them affect the physiology of the host but are not essential for virus replication. These included *protein kinases 1 and 2*, viral *superoxide dismutase*, *DNA polymerase*, *desmoplakin*, *inhibitor of apoptosis 1 and 2*, *UDP-glycosyltransferase*, *viral fibroblast growth factor*, *viral ubiquitin*, *snf2 global transactivator*, *methyltransferase*, *viral chitinase A*, *viral cathepsin*, and *protein tyrosine phosphatase*. In addition, other baculovirus genes with other functions or essential for virus replication also had homology to *Bombyx mori* genes, indicating broad acquisition of genes from lepidopteran hosts.

A number of viral genes appear to be devoted to relieving translational blocks imposed by the host to prevent the translation of viral products, many in the eIF2 α – PKR pathway. Some baculoviruses encode protein kinase 2 (PK2), which inhibits eIF2 α by binding to the N-lobe of PKR. This forms a pseudokinase that targets the insect heme-regulated inhibitor-like eIF2 α kinase thereby enhancing virus production. It was concluded that the viral PK2 may have been acquired from a lepidopteran host to compete for shared translation-specific factors.

One pathway used by several viruses for replication or spread within or away from the infected cell is actin polymerization. Baculoviruses encode P78/83, a capsid-associated protein with Wiskott-Aldrich syndrome protein-like domains similar to actin nucleating promoting factors. P78/83 is necessary for virus replication. It is a functional factor that activates the host Arp2/3 (proteins that regulate the actin cytoskeleton, serving as nucleation sites that seed the origin of new actin filaments) after it is trafficked to the nucleus of infected cells, promoting actin polymerization. Baculoviruses can mobilize by assembling G-actin monomers from the host into F-actin filaments. Baculoviruses use actin to move to the nucleus of cells and to egress from the nucleus of cells and transit through the cytoplasm before budding. Furthermore, nuclear F-actin filaments can embed into the nuclear envelope, disrupt it and facilitate virus egress. Although nuclear actin in eukaryotes and its roles in chromatin remodeling, transcription and processing of RNAs have been more widely studied in recent years, the role of nuclear actin in virus replication is still in the discovery phase. Thus, baculoviruses have co-opted a common cytoplasmic function to promote actin assembly in the nucleus of cells and as an instrument that disrupts nuclear envelope integrity for viruses to transit into the cytoplasm rather than exiting through the nuclear envelope pores.

Baculovirus genes acquired from the host may supply functions that optimize virus replication or facilitate host expansion; however, in some cases, the acquired gene has been co-opted to carry out a new essential function. The envelope fusion protein F of some baculoviruses may have been derived from an insect gene, as indicated by the similarity with the F predicted proteins of three *Drosophila* species and the mosquito *Anopheles gambiae*. Alternatively, baculoviruses may have acquired the *f* gene from *f*-like genes carried in endogenous retroviruses embedded in insect hosts.

Baculovirus Host Range Genes

The host range of baculoviruses has been explored in insects and in cells. Studying the replication of baculoviruses in diverse insects defined alternative hosts in the laboratory that were permissive for virus replication in addition to the host from which the virus was isolated. This defined a relatively broader host range for some members of the *Baculoviridae*. Surveying infected individuals in nature is expanding our knowledge of the host range of each virus, while genomic sequencing of baculoviruses is further defining viral species that can be found in more than one host. In cells, host determining factors that expanded the host range of a virus have been described, and it appears that baculoviruses have acquired genes that allow more efficient replication or transmission in some hosts. Baculoviruses can be considered generalists, infecting several insects, or specialists, infecting a small number of insects, depending on the species. In general, they have a relatively narrow host range, a characteristic that is not optimal to agriculturists needing to combat more than one insect pest during a growing season but advantageous in that they do not target beneficial insects (*e.g.*, pollinators). AcMNPV was originally isolated from the host species *Autographa californica* and can infect over 35 insect species, while genetically similar viruses isolated from other species (*e.g.*, BmNPV isolated from *Bombyx mori*) infect slightly over a dozen insect species in a laboratory study but has only been successfully isolated from *Bombyx mori* in the wild. This poses the question of whether additional or specific genes allow some viruses to expand their host range.

Having the appropriate host receptor binding protein for viral attachment may allow virus entry into cells, but successful and complete virus replication may not be supported unless viral genes that properly interact with host genes and defeat, reduce or circumvent immune responses are effective. Several baculovirus genes have been characterized that are necessary for a productive infection in another insect host or cell line derived from a different host, suggesting acquisition of genes occurred to expand the host range of a virus. These genes include six factors with seemingly little in common, either structurally or functionally, which suggests that they are affecting different mechanisms to alter host range, and viruses may have acquired these genes at different times. Briefly, the six baculovirus genes defined as host range genes are described as follows. (1) The viral *helicase p143* (*ac95*) is a conserved gene in all baculovirus genomes. Its product, P143, is a helicase required for viral DNA replication and late gene expression. Changing two amino acids in P143 allowed AcMNPV to be lethal in non-permissive *Bombyx mori* larvae. (2) The AcMNPV *p35* gene (*ac135*), an apoptosis inhibitor gene, carried by some baculoviruses, is necessary to prevent apoptosis in cell lines derived from *Spodoptera frugiperda* but not necessary for successful replication in cell lines derived from *Trichoplusia ni*. Mutant viruses lacking *p35* are significantly less lethal than wild-type in *S. frugiperda* larvae but not in *T. ni* larvae. Baculoviruses have other apoptosis inhibitors (P49, IAPs) and in some cases more than one gene copy is present. This indicates that virus replication is dependent on blocking the process of apoptosis in some species, but not others, and several factors may be encoded to ensure the proper host-virus interactions. (3) The *late expression factor-7* gene (*lef-7*, *ac125*) enhances viral late gene expression and DNA replication. Its deletion affects virus replication in some hosts and cell lines (SF-21) but not in others (TN-368). The BmNPV *lef-7* showed little or no replication defects in BmN cells or *B. mori* larvae. (4) The *host cell factor-1* (*hcf-1*, *ac70*) is found only in some baculoviruses. It stimulates a late viral promoter in some cell lines (*e.g.*, TN-368), where it is necessary for optimal virus DNA synthesis and virion production. Deletion of *hcf-1* affects mortality of *T. ni* larvae. It is not required in SF-21 cells and a virus with a deletion of *hcf-1* can replicate in SF-21 cells and *S. frugiperda* larvae, but protein synthesis shut-off was impaired. Expression of

HCF-1 allowed *Hyphantria cunea* MNPV to replicate in non-permissive TN-368 cells. (5) The *host range factor-1* gene, *hrf-1*, is a gene encoded by *Lymantria dispar* MNPV. When expressed in AcMNPV, it allows AcMNPV to replicate in semi-permissive cells derived from *L. dispar* and in *L. dispar* larvae by allowing translation to proceed. A homolog of *hrf-1* is also carried by *Orgyia pseudotsugata* MNPV, a virus that replicates in *L. dispar*, suggesting acquisition of the gene was necessary for these viruses to productively infect *L. dispar*. However, the OpMNPV *hrf-1* did not allow AcMNPV to replicate in *L. dispar*-derived cells, suggesting differences in functionality or in the interactions with other host or viral factors. (6) The AcMNPV *ie-2* (*ac151*) gene is a transcriptional transactivator in the presence of the powerful transactivator IE-1. IE-2 also enhances viral DNA replication and arrests the cell cycle. It is not necessary in *T. ni*-derived cells compared to *S. frugiperda*-derived cells, but AcMNPV mutants lacking *ie-2* still have diminished replication in *T. ni*. It is possible that specific genes encoded by some baculoviruses optimize virus replication in some hosts and depending on host innate immunity, the presence of such genes may determine if virus replication is successful or not. The inability to test alternative hosts in some cases precludes obtaining a complete picture of specific gene advantages in those hosts. Altogether, various auxiliary genes functioning at the levels of transcription, translation and DNA biosynthesis are often non-essential for the ability of a virus to infect some hosts but essential in others. Their conservation in some virus species may be indicative of efficacious infectivity in specific hosts. Acquisition of host range genes also suggests that viral genes interact with specific host genes to augment viral replication.

Virus Defense and Resistance to Baculoviruses

Several genes that block apoptosis are encoded by baculoviruses to prevent host cell death and thereby allow virus replication. These genes work at different steps in the apoptotic pathway, suggesting different acquisitions during their evolution and the importance of carrying genes that effectively block apoptosis. The gene *p35* was discovered in a spontaneously generated mutant of AcMNPV that had a mutation within *p35*. A virus with this mutation prevented specific cells (*i.e.*, Sf-21) from undergoing apoptosis during infection. The *p35* gene product, P35, inhibits effector or executioner caspases, cysteine-aspartic proteases, by binding to them in a stoichiometric manner and preventing proteolytic cleavage of their aspartic acid-containing substrate proteins. A similar gene product, P49, is encoded by some baculoviruses but, works earlier in the apoptotic cascade than P35, inhibiting initiator caspases. Thus, P49 can rescue *p35* mutant viruses by working upstream of P35. Inhibitors of apoptosis genes, *iaps*, have homologs widespread in metazoans. The viral IAP from *Orgyia pseudotsugata* multiple NPV, Op-IAP3, binds the insect IAP, stabilizing it and preventing its transitory ability to block cell death. This ensures effective cell death and virus replication.

The baculovirus *Hemileuca* sp. NPV encodes a functional serpin. Serpins are serine proteinase inhibitors and mediate the regulation of proteinases involved in the phenoloxidase process, a process that melanizes tissues or pathogens in invertebrates and has an important role in immune response and tissue healing. The baculovirus serpin, Hesp018, inhibited trypsin, chymotrypsin and plasmin. In addition, it blocked bacteria-activated phenoloxidase responses in the hemolymph of the tobacco hornworm *Manduca sexta*. Expression of *hesp018* in AcMNPV resulted in increased budded virus production in Sf9 cells and increased virulence in *T. ni* larvae. Other baculoviruses encoding serpin-like genes have not been discovered, indicating that *Hemileuca* sp. NPV has a singular advantage to encode *hesp018* and replicate in its host. The viral serpin gene differs from noctuid and bombycoid serpin-4 genes. Thus, it was concluded that *hesp018* was either acquired long ago and slowly diverged or it was a recent acquisition and the gene changed at a fast rate compared to the cellular homolog. Other baculoviruses may have other genes that help control insect humoral immunity.

For many years it was thought that an advantage of using baculoviruses as pest control agents of important agricultural and forestry plants was that the pests would have difficulty in developing resistance to the viruses they had co-evolved with for many years. However, in recent years, it has been found that a specific viral gene in the *Cydia pomonella* granulovirus involved in transcription, *pe38*, is necessary for infectivity in codling moths. Resistant insects were identified that were infected by a virus carrying a mutation within *pe38*. Acquired host resistance in codling moths has also been documented and has been mapped to dominant gene mutation(s) in sex-linked chromosomes, but the specific resistance genes have not yet been identified. Although insects have acquired resistance to virus isolates, indicating adaptation, this is an area that deserves more attention and has been understudied. In the past, the limitation of lepidopteran genetic tools and genomic sequences has hindered developments in the field, although this is now beginning to change.

In addition to baculovirus genes that allow a productive infection in additional hosts and that interfere with the host immunity, other baculovirus genes that aid in other processes, including virus assembly, viral DNA replication, host physiology manipulation, and virus dispersal have homologs in other organisms (Fig. 2).

Concluding Remarks

A significant percentage of baculovirus genes have counterparts in cellular organisms, conveying the close interaction between the two and showing how changing environmental situations leads to gene exchanges to benefit one and counteract the other. Studies on baculovirus gene lineages indicate that baculoviruses have usurped many of their genes from their insect hosts (some specifically traced to lepidopterans) or bacteria. Homologs of many baculovirus genes are found in insects, prokaryotes, other

eukaryotes and archaea, heightening the richness of tools and strategies acquired through evolution. Thus, baculoviruses have evolved to contain a toolbox suitable to replicate in diverse insect hosts. Host-acquired genes include genes important for immunity, spread, genome replication, transcription and other processes. Detailed analyses of the phylogenetics of each gene will provide a more comprehensive picture as to when gene acquisition took place, the cellular organism from which genes were acquired, additional host interactions, and insights into gene function. The fluidity of gene transfer suggests the need for baculoviruses to optimize their replication strategies in different hosts through time and following diverse burdens.

Genes from a host or from another organism present in a host can be acquired by a virus to meet selective advantages depending on the environmental cues. These can include fighting host defenses, mounting offenses to debilitate host processes and host range expansion. Viruses can use different strategies to further their replication capabilities: mimicry, where gene products mirror host proteins and serve as decoys; co-option, the adaptation of different functions of an original host protein to aid in virus replication; and gene acquisition, to have an additional function not previously encoded. Altogether, gene acquisition adds tools to a viral toolbox that can be effectively used to either defeat the host or enhance virus replication.

Viral genes acquired from other organisms generally have low similarity to and simpler domains than the cellular gene, making it difficult to define their origin. In addition, viral genes incur additional and more rapid changes than host proteins, making it harder to discern the directionality of horizontal gene transfer events. Co-opted genes can acquire a different function, further muddying identification of gene origins. Genes transferred between viruses and their hosts have co-evolved in an impending and continuous arms race for survival of each. Virus-host networks can be studied using molecular methods that provide a footprint of gene acquisition. More specifically, the transferal of genes and relationships (genetic or behavioral) between viruses and their hosts can be studied using diverse systems, including high-throughput methods and genome-wide screens that map host genes that affect various viral replication steps; next generation sequencing of host and viral genomes combined with detailed and structure-based phylogenetics to define evolutionary lineages; molecular interactomes using the yeast two-hybrid system, mass spectrometry complex identification or computational algorithms to identify the interactions between factors; identification of microbiome components to further define the interactions and gene transfer between organisms and viruses; and host experiments supporting *in vitro* ones, when possible. The amalgamation of various methods will help define the cross-talk and mobility of genes between viruses, their hosts, host microbiomes and additional parasitic organisms replicating in a host. Co-option of genes aids in our understanding of the different potential functions of gene products in different settings throughout evolution.

Classification (Compact)

Family: *Baculoviridae*; Genera: *Alphabaculovirus*, *Betabaculovirus*, *Deltabaculovirus*, *Gammabaculovirus*; Species: *Autographa californica multiple nucleopolyhedrovirus* (for example).

Virion Structure

Virion structure is complex. Capsids have helical symmetry (200–450 nm in length, 30–100 nm in diameter). Two enveloped forms of virus are produced: budded and occluded viruses.

Genome

One double-stranded circular DNA genomes, 80- to 180-kilobasepairs in length.

Replication Cycle

Insects ingest occlusion bodies containing occlusion-derived viruses and released virions infect midgut epithelial cells. Following budding from midgut cells, the budded virions infect insect cells in the hemocoel, including hemocytes and cells in various tissues. Infected cells produce more budded virus for systemic spread within an insect and occluded virus for insect-to-insect spread. Upon host death, occluded virions are dispersed for new hosts to ingest. In a few baculoviruses, particularly *deltabaculoviruses*, the infection is midgut restricted.

Epidemiology

Insects acquire infection through consumption of the occluded form of the virus as a contaminant of their food. In some cases, they can be transmitted transovum and transovarially. Baculoviruses have a relatively narrow host range and can cause epizootics, altering insect population dynamics.

Pathogenesis

The tissue and cuticle of infected insects liquefies through the concerted activity of baculoviral chitinase and cathepsin enzymes, dispersing occluded virus. Cuticle discoloration may be apparent. At the cellular level, cells round up and the nucleus is enlarged. At very late times post infection, cells exhibit occlusion or granular bodies, containing sets of one enveloped or more co-enveloped nucleocapsids.

Diagnosis

Infected insect larvae have a lighter color and their cuticle is fragile, easily breaking to the touch and dispersing virus. Infected larvae climb to the top of plant foliage, a virus-induced behavior called *Wipfelkrankheit* or tree-top disease, and this allows more efficient virus spread on the foliage below, upon larva liquefaction or melting.

Glossary

Budded virus (BV) One of the two virion types of baculoviruses that is produced when nucleocapsids bud from the plasma membrane of an infected cell and mediates the systemic cell-to-cell spread within the infected insect.

Granule The OB of granuloviruses (plural granules).

Granulin The major protein in granulovirus OBs.

Granulovirus (GV) Name used for all baculoviruses that form granular-shaped OBs of which the major matrix protein is granulin, comprising all viruses from the genus *Betabaculovirus*.

Nucleopolyhedrovirus (NPV) Name used for all baculoviruses that form polyhedral-shaped OBs of which the major matrix protein is polyhedrin, comprising all

viruses from the genera *Alphabaculovirus*, *Deltabaculovirus* and *Gammabaculovirus*.

Occlusion body (OB) Proteinaceous crystalline structure protecting the infectious ODVs, responsible for horizontal insect-to-insect spread.

Occlusion derived virus (ODV) One of the two virion types of baculoviruses that is assembled in the nucleus where nucleocapsids obtain an inner nuclear membrane-derived envelope, and that becomes occluded within the proteinaceous crystalline matrix of the occlusion body.

Polyhedrin The major protein in nucleopolyhedrovirus OBs.

Polyhedron The OB of nucleopolyhedroviruses (plural polyhedra).

Historical Perspective

The history of the discovery of baculoviruses is closely linked to the development of the silk industry, which originated in China and arrived in Europe during medieval times. The dramatic effect of baculoviruses on insect hosts was already described in 1527 by Marcus Hieronymus Vida, bishop of Alba in Italy, long before the identity of baculoviruses was revealed. His poem “*Bombycum*” (The silkworm) includes a description of liquefying silkworms (caterpillars of the silk moth *Bombyx mori*), later known as jaundice disease and characteristic for baculovirus infections. After the invention of light microscopy, Maestri and Cornalia independently described refractile occlusion bodies which were commonly polyhedron shaped, leading to the naming of the disease observed in the silkworms as ‘polyhedrosis’ by the mid-1800s. Glaser, Paillot, and colleagues, between 1913 and 1928, demonstrated that the polyhedrosis disease of caterpillars was due to a filterable agent and therefore must have a viral etiology. With the perfection of insect tissue culture methodology, William Trager in 1935 reported on the ability of the Grasserie virus, now known as *Bombyx mori* nucleopolyhedrovirus (BmNPV), to replicate in silkworm tissue culture cells. This led to the opportunity of studying the replication of these viruses under more controlled conditions than possible when working with whole insect larvae and free of other microbial agents.

Nomenclature, Taxonomy, and Classification

The family *Baculoviridae* comprises insect viruses with 80–180 kbp circular double-stranded DNA (dsDNA) genomes encoding 100–200 proteins. The family name is derived from the rod-shaped (baculum, Latin for stick) nucleocapsids. In the 10th report of the ICTV (2019, as per see “Relevant Website section”) a total of 82 baculovirus species are recognized and a further 19 tentative species are listed (Table 1). Four genera are distinguished within the *Baculoviridae*, based on phylogeny, genome characteristics,

Table 1 Number of species per baculovirus genus

Genus	Member species (ICTV) ^a	Related, unclassified species
<i>Alphabaculovirus</i>	53	15
<i>Betabaculovirus</i>	26	0
<i>Deltabaculovirus</i>	1	2
<i>Gammabaculovirus</i>	2	2
Total	82	19

^aBased on the 10th report of the International Committee on Taxonomy of Viruses (ICTV) (2019, as per https://talk.ictvonline.org/ictv-reports/ictv_online_report/ds dna-viruses/w/baculoviridae).

host range and occlusion body (OB) morphology; *Alphabaculovirus* (lepidopteran-specific nucleopolyhedroviruses (NPVs)) with 53 species, *Betabaculovirus* (lepidopteran-specific granuloviruses (GVs)) with 16 species, *Deltabaculovirus* (dipteran-specific NPVs) with one species, and *Gammabaculovirus* (hymenopteran-specific NPVs) with two species. Based on phylogenetic inferences but not yet recognized taxonomically, lepidopteran-specific alphabaculoviruses are further divided into Group I and Group II alphabaculoviruses (Fig. 1). These two groups differ significantly in gene content, most notably Group I alphabaculoviruses encode GP64 as the BV fusion protein, whereas Group II alphabaculoviruses encode Fusion protein (F) but lack *gp64*.

Baculoviruses are unique among viruses in having a biphasic replication cycle with two morphologically distinct virion types, budded viruses (BVs) and occlusion derived viruses (ODVs) (Fig. 2). Early in infection, BVs are produced when newly formed nucleocapsids bud out of the insect cell, obtaining an envelope from the cell membrane (Fig. 3). BVs are responsible for cell-to-cell transmission within the infected insects (as well as in cell tissue culture). Later in infection, ODVs are formed in the host nucleus where nucleocapsids obtain a membrane from microvesicles derived from the inner-nuclear membrane. The ODVs are subsequently embedded in a polyhedral (NPV) or granular (GV)-shaped proteinaceous crystalline matrix, forming viral OBs. The occlusion body form is responsible for horizontal insect-to-insect spread. ODVs may have one or several nucleocapsids within a single envelope, depending on the species of baculovirus, forming single (S) or multiple (M) NPVs, respectively.

Baculoviruses infect larval stages of species belonging to the insect orders Lepidoptera, Diptera (family Culicidae) and Hymenoptera (suborder Symphyta). NPVs are found in these three insect orders, while GV is restricted to the Lepidoptera. Baculoviruses are normally named according to the initial host from which they were isolated and the type of OB/ODV associated with it. While this might cause some confusion, since the same virus might occur in a range of insect species, this approach is still applied today. Originally baculovirus abbreviations used the first letter of the genus and species name of the host insect followed by NPV or GV depending on the type of occlusion body. Hence the MNPV from the alfalfa looper *Autographa californica* is abbreviated as AcMNPV and the MNPV from *Choristoneura fumiferana* is abbreviated as CfMNPV. Those baculoviruses which have historically had a two-letter species code continue to maintain those abbreviations. However, as more baculoviruses were being described, a two-letter species designation system was untenable and now a four-letter species identification based on the first two letters of each of the genus and species names of the host insect from which the virus was first isolated is used. Hence the NPV from *Helicoverpa armigera* is abbreviated as HearNPV and that from *Neodiprion lecontei* is abbreviated as NeleNPV. If identical letterings might result, the third or later letters are used instead of the second, as seen for SpltNPV for an NPV from *Spodoptera litura* that was chosen since SpliNPV was already used for an NPV from *Spodoptera littoralis*. Although the S and M are useful morphological descriptors in the names indicating if nucleocapsids exist either singly or in multiples within ODV virions, they do not appear to have any taxonomic relevance and so in more recently described baculoviruses these designations have been dropped but have been maintained for those baculoviruses in which there is a strong historical precedence. To determine whether an isolate belongs to an existing virus species or should be the basis of a new species requires biological and molecular information. A Kimura two-parameter method including the information from all 38 baculovirus core genes can be used for species demarcation, along with additional information such as host range and genome organization.

Morphology

Viruses in all four baculovirus genera have two structurally and biochemically distinct virion phenotypes (BVs and ODVs; Fig. 2) and a biphasic replication cycle (Fig. 3). These virions consist of cylindrical, rod-shaped, nucleocapsids contained within a lipid bilayer envelope. The nucleocapsids contain the dsDNA genome and range in size from 30 to 60 nm in diameter and, depending on the size of the genome, 250–300 nm in length. They consist of a single circular supercoiled dsDNA packed into a protein capsid. The nucleocapsids have a flat base structure on one end and a nipple-like cap on the other end. BVs contain a single nucleocapsid surrounded by a loose-fitting envelope. The BV envelope, obtained from the cellular plasma membrane during budding, is modified at the nipple end by the occurrence of spikes or peplomers consisting of viral glycoproteins such as GP64 or F proteins. ODVs contain one or several nucleocapsids present in a parallel array, enveloped in a membrane derived from the inner nuclear membrane in the nucleus (for alphabaculoviruses) or in the nuclear-cytoplasmic milieu after loss of the nuclear membrane (for betabaculoviruses). ODVs are embedded in paracrystalline occlusions forming either polyhedra (NPVs) or granules (GVs). Polyhedra are roughly cuboidal (although other shapes have been described) containing multiple ODVs. Alphabaculovirus OBs are 0.15–5.0 µm in size and contain many ODVs and,

Fig. 1 Schematic representation of baculovirus phylogeny, showing the different genera and other (sub) groups, based on the baculovirus core-genome phylogeny of Thézé, J., Lopez-Vaamonde, C., Cory, J.S., Herniou, E.A., 2018. Biodiversity, evolution and ecological specialization of baculoviruses: A treasure trove for future applied research. *Viruses* 10, 366. The original phylogeny was obtained from maximum likelihood inference analysis of the concatenated amino acid alignment of 37 baculovirus core genes. Values at nodes represent bootstrap values (100 replicates).

depending on the virus species, containing either single (S) or multiple (M) nucleocapsids. Betabaculovirus OBs (granules) are ovoid cylindrical in shape and much smaller in size, measuring 0.12–0.50 μm . Each granule characteristically contains a single virion each containing a single nucleocapsid. Within the genus *Deltabaculovirus* only a single species has been classified, *Culex nigripalpus* nucleopolyhedrovirus. The ODVs of CuniNPV are embedded in an OB composed of a crystalline matrix of a viral protein with no homology to polyhedrin or granulins. The OBs range in size from 0.5 to 5.0 μm and contain few (1–4) or many (> 50) ODVs depending on the strain of the virus. Gammabaculovirus OBs contain multiple ODVs, each containing a single nucleocapsid. Genome sequences of viruses from the three classified species in this genus revealed that they do not encode an envelope fusion protein as found in other baculoviruses, questioning the role of the BV phenotype in the biology of gammabaculoviruses.

Genomes, Gene Content, Organization

Baculovirus genome size varies considerably for the currently sequenced genomes, ranging from 81,755 bp for the gammabaculovirus *Neodiprion lecontei* NPV (NeleNPV), encoding 89 open reading frames (ORFs) to 178,733 bp for *Xestia c-nigrum* GV (XecnGV), encoding 181 ORFs. Baculovirus ORFs are defined as those encoding proteins of at least 50 amino acids with minimal (< 75 nucleotides) overlap with each other. The guanine-cytosine (GC) content of baculovirus genomes ranges from 32.4% for *Cryptophlebia leucotreta* granulovirus (CrleGV) to 57.5% for *Lymantria dispar* multiple nucleopolyhedrovirus (LdMNPV). Baculovirus genes are distributed on both strands, in both orientations. The gene order does not follow a general pattern but is conserved among related baculoviruses. Intergenic regions are short and promoters and/or 3' untranslated regions of flanking genes

Fig. 2 Baculovirus virions and nucleocapsids. The two baculovirus virion phenotypes, occlusion derived virus (ODV) and budded virus (BV), are illustrated as diagrams with shared and phenotype-specific components. Taken from the International Committee on Taxonomy of Viruses (ICTV) website (<https://talk.ictvonline.org/>).

Fig. 3 Schematic representation of the alphabaculovirus infection cycle. A lepidopteran larva ingests plant material contaminated with occlusion bodies (OBs) (a). The OBs dissolve in the alkaline midgut, resulting in release of the occlusion derived viruses (ODVs). The ODVs pass the peritrophic membrane and bind to and fuse with the midgut epithelial cell membrane, after which the nucleocapsids enter the cell (primary infection) (b). The parental nucleocapsids migrate towards the nucleus for the first round of replication forming new nucleocapsids that migrate to the plasma membrane, or directly migrate to the plasma membrane. The nucleocapsids bud out of the cell, acquiring an envelope from the plasma membrane which contains the viral fusion protein (GP64 or F-protein; depicted as red spikes), forming budded viruses (BVs) (c). BVs are responsible for cell to cell spread (secondary or systemic infection). The BVs infect surrounding columnar or regenerative midgut cells via endocytosis. From the midgut, the infection is spread to other larval tissues via the hemolymph and the trachea (d). At the very late stage of infection, the nucleocapsids remain inside the host cell nucleus to be enveloped by a microvesicle membrane that is derived from the inner-nuclear membrane, forming new ODVs. These are subsequently occluded in a protein matrix, forming new OBs. Finally, the cells lyse and the exoskeleton is degraded, resulting in liquefaction of the larvae and release of the OBs into the environment. 1. Occlusion body; 2. Occlusion derived virus; 3. <i>ac78</i>	Interacts with sulfhydryl oxidase	
<i>ac81</i>	Non-structural protein of unknown function	

^aName in brackets refers to the gene number on the AcMNPV genome, the first baculovirus complete genome to be sequenced.

may overlap. A characteristic of most baculovirus genomes is the presence of several homologous repeat regions (*hr*'s), consisting of repeats of short, often palindromic sequences, typically 30–40 nt in length. Cell culture assays revealed that *hr*'s function as origins of replication and enhancers of transcription.

Comparison of all fully sequenced baculovirus genomes of all four genera has revealed a set of 38 core genes (Table 2), which are shared among all baculovirus species. Most of these genes encode proteins involved in basic functions, including DNA replication, gene transcription, progeny virion assembly and structure and oral infectivity. Additional sets of genes are shared within genera, or among groups of related baculoviruses. Other genes are unique to one or a few baculovirus species.

Baculovirus transcription is temporally regulated into four phases: immediate early, delayed early, late and very late. Expression of genes in one phase is dependent on the expression of genes in the preceding phase. The expression of some genes extends through several phases. Early genes are expressed prior to DNA replication and are transcribed by host RNA polymerase II. Late and very late genes are transcribed by a viral RNA polymerase and the very late genes comprise two highly expressed genes: the polyhedrin or granulins gene encoding the OB matrix protein and the p10 gene encoding a 10 kDa protein that forms fibrillar structures important for OB formation and release.

Evolution

Baculoviruses are related to other insect viruses with large dsDNA genomes, including nudiviruses (*Nudiviridae*), bracoviruses (endogenized viruses that are derived from the nudiviruses) (genus *Bracovirus* from the family *Polydnnaviridae*) and hytrosaviruses

(*Hytrosaviridae*), all of which are exclusively pathogenic to arthropods, harbor rod-shaped enveloped nucleocapsids and replicate in the nucleus. Nudiviruses and baculoviruses are sister groups, bracoviruses are nested within the nudiviruses and hytrosaviruses are an outgroup. Nudi- and baculoviruses first evolved around 310 Mya in the Paleozoic Era during the Carboniferous Period with the first insects. Further virus diversification is linked to the diversification of insect orders. More distantly related to these insect viruses are whispoviruses, infecting shrimp, of the family *Nimaviridae*.

The baculovirus lineage appeared shortly after the appearance of holometabolous insects – insects with larval stages undergoing complete metamorphosis. Baculoviruses have been characterized in only holometabolous insects from the orders Diptera, Hymenoptera and Lepidoptera. Phylogenetic analyses revealed ancient co-evolution between baculoviruses and these insects, and also showed that the baculovirus ancestor was already specialized to infect larval stages of holometabolous insects.

Within the baculoviruses, the four genera form distinct and major lineages, reflecting co-evolution of baculoviruses and their insect hosts. The deltabaculoviruses are the most ancient baculoviruses and are ancestral to the gammabaculoviruses. Both are ancestral to the lepidopteran-infecting alpha- and betabaculoviruses, which are sister groups. Furthermore, alphabaculoviruses are further subdivided into two groups, the monophyletic Group I alphabaculoviruses that is nested within the Group II alphabaculoviruses (Fig. 1). Two additional subgroups, clade Ia and Ib can be distinguished within Group I alphabaculoviruses, while clade IIa, IIb and IIc are found within Group II alphabaculoviruses (Fig. 1). Phylogenetic analyses of whole genome sequences have greatly expanded our understanding of baculovirus diversity and evolution and showed that host shifts played a major role in the diversification of baculoviruses. Colonization of new ecological niches has sometimes led to viral radiation. Furthermore, extensive horizontal gene transfer between baculoviruses and insect hosts and between baculoviruses and other viruses has occurred.

Infection Cycle

Insects become infected by baculoviruses when an insect larva consumes viral OBs during feeding (Fig. 3). The OBs dissolve rapidly in the alkaline environment of the larval midgut, releasing the ODVs. In order to access the target columnar midgut epithelial cells, the released virus must first penetrate the peritrophic membrane (a mesh of fibers consisting of chitin fibrils linked to glycoproteins and proteoglycans) lining the gut. This process is facilitated by enhancins (metalloproteases), which are encoded by most GV and some NPV. Enhancins are also thought to increase the fusion efficiency between the viral and cellular membranes during infection. The ODV envelope fuses with the host cell plasma membrane, releasing the nucleocapsids into the cytoplasm. Fusion is preceded by binding of the ODV to the microvilli by a specific, protease-sensitive receptor. Attachment and fusion requires a set of proteins, called *per os* infectivity factors (PIFs). These proteins are encoded by core genes, and currently eight *pif* genes are known (Table 2). The released nucleocapsids migrate along cytoplasmic actin filaments to nuclear pores. The nucleocapsid is uncoated either at the nuclear pore or as it enters the nuclear pore to release the DNA core into the nucleus. In the nucleus, transcription of viral genes is initiated, followed by DNA replication, late gene transcription, viral protein translation and nucleocapsid assembly. Nucleocapsids are transported to the basal site of the infected midgut cell where they form BVs by budding out of the cell, thereby acquiring an envelope from the host cell plasma membrane which has been modified to contain viral proteins such as GP64 or F. BVs are responsible for cell to cell spread within the insect host (secondary or systemic infection). Cell entry of BVs occurs via clathrin-mediated endocytosis. Most baculoviruses disseminate throughout the insect infecting all tissues, via the hemolymph (after passing the basal lamina) and/or via the tracheal system. For some baculovirus species, including some GVs, gammabaculovirus and deltabaculovirus, infections are limited to host midgut epithelial cells. The role of BVs in these infections, if any, remains unclear.

At the very late stage of infection, cells switch to ODV production and OB formation (Fig. 3). Within the nucleus, nucleocapsids acquire an envelope from the inner-nuclear membrane. The virions then become occluded within occlusion bodies (polyhedra or granules). This systemic infection is so effective that following death, up to 25% of the larval mass is due to polyhedra. The late expressed virally encoded enzymes chitinase and cathepsin aid cell lysis and exoskeleton degradation, liquefying the larvae and releasing the OBs into the environment. These enzymes are not encoded by baculoviruses whose infection is limited to the midgut. For these, the virus particles are released by sloughing of infected midgut cells and by excretion of viruses.

Baculovirus Transmission and Host Behavioral Manipulation

OBs are highly persistent in the environment. OBs can even survive passage through the gastrointestinal tract of birds, facilitating their long distance dispersal. Baculoviruses also ensure enhanced dispersal by modifying host behavior. Baculovirus-induced behavioral changes were first reported in 1891 by Hofmann, representing the oldest written record of parasitic manipulation of host behavior. Infected *Lymantria monacha* larvae lost their appetite and migrated to the top of trees where they liquefied, termed by Hofmann as “Wipfelkrankheit” (tree-top disease). Such climbing prior to death has been observed for a range of baculovirus-caterpillar combinations, and infected caterpillars were found to move towards the light. In addition, infected caterpillars may show increased locomotion behavior (hyperactivity or hypermobility). These behavioral changes are thought to enhance viral spread, by increasing the area over which the virus is distributed and by making deceased caterpillars more visible to predators including birds. Recent studies have revealed part of the molecular mechanisms underlying these virus-induced behavioral changes. A virally encoded protein tyrosine phosphatase (PTP) is involved in the induction of hyperactivity in BmNPV-infected

B. mori larvae as well as in AcMNPV-infected *S. exigua* larvae. Since *ptp* is restricted to Group I alphabaculoviruses, most likely other viral genes are involved as well for hyperactivity in non Group I alphabaculoviruses. Furthermore it was found that the *egt* gene, present in nearly all baculoviruses and encoding an ecdysteroid UDP-glucosyl transferase (EGT), plays a role in baculovirus-induced tree-top disease in certain virus-host combinations. In LdMNPV-infected *L. dispar* larvae, *egt* is involved in the induction of tree-top disease, however, the *egt* gene of AcMNPV did not induce tree-top disease in *S. exigua* or *Trichoplusia ni* larvae. Baculoviruses apparently possess multiple mechanisms to modify host behavior, dependent on the specific virus-host combination studied.

In addition to horizontal transmission of OBs, by either consumption of OB contaminated food or by cannibalism, baculoviruses are also vertically transmitted. Natural and laboratory populations often harbor covert baculovirus infections. The molecular basis for covert baculovirus infections is currently unclear, however, these covert viruses can be vertically transmitted from parents to offspring. Therefore baculoviruses have a mixed-mode transmission, with both horizontal and vertical transmission, possibly allowing virus persistence when opportunities for horizontal transmission is limited. Covert infections can be re-activated to produce lethal disease, followed by horizontal transmission.

Baculovirus Expression Technology

The discovery in the 1980s that the polyhedrin promotor of AcMNPV could be exploited to produce high levels of recombinant proteins in insect cells marks the beginning of the baculovirus expression vector (BEV) system. Since then, baculovirus-based expression technology has developed extensively and is now widely used to produce proteins of interest and commercial vaccines for both human and veterinarian use, like the Circumvent®PCV-M G2 vaccine developed by Merck against both circovirus and *Mycoplasma hyopneumoniae* in pigs, and the Cervarix vaccine against human papillomavirus. As a BEV is a eukaryotic expression vector, many of the common post-translational modifications that occur to produce mammalian proteins also occur in the BEV system, although glycoproteins produced in insects generally display more uniform, but less complex-glycans than mammals. Attempts are being taken to further “mammalianize” glycoprotein processing in insect cells to further improve the authenticity of baculovirus-expressed mammalian proteins.

Furthermore, recombinant baculoviruses are used as gene delivery vectors for mammalian cells and as expression vectors for adeno-associated virus (AAV)-based gene therapy products.

Baculoviral Insecticides

Since their discovery, baculoviruses have been studied mainly for their value as potent, biologically based insect pesticides. Baculoviruses are naturally occurring pathogens, with therefore a much smaller environmental impact compared to chemical insecticides in the management of agricultural and forest pest insects. Furthermore, baculoviruses are highly specific with a limited host range, have no negative effects on non-target organisms and can be mass-produced, formulated, packaged and stored. More than 60 baculovirus-based pesticides have been utilized worldwide to control diverse insect pests. One of the most effective ones include *Anticarsia gemmatilis* MNPV (AgMNPV) which was successfully used to control the velvet bean caterpillar *A. gemmatilis*, an abundant soybean pest in Brazil and other South American countries. The use of AgMNPV reduced larval populations by 80%, the same level as for insecticide treatment. Other highly successful examples of baculovirus insecticides include *Cydia pomonella* GV (CpGV) to control the codling moth *C. pomonella* in apples, pears and walnuts, *Helicoverpa armigera* NPV (HearNPV) to control the cotton bollworm *H. armigera*, a highly polyphagous pest worldwide and *Spodoptera exigua* MNPV (SeMNPV) to control the beet armyworm *S. exigua*, a highly polyphagous and widely distributed pest both in the field and in greenhouses.

Although baculoviruses have been successfully applied, they have some limitations compared to other (chemical) insecticides, including a slower speed of kill, a very narrow host specificity (which may hinder commercialization), a susceptibility to UV light and high production costs (large scale production still relies on in vivo systems). In addition, resistance against baculoviruses may develop, as occurred in some *C. pomonella* populations in Europe. Since the speed of kill is much faster for smaller instars (and since older instars may bore into stems or fruits being unreachable for any pesticide), the effectiveness of baculovirus application can be optimized by proper monitoring in the field enabling a timely application. To further lower the time to kill and to increase the efficacy of baculoviruses, recombinant baculoviruses have been developed in the laboratory, by deleting baculovirus genes, by adding genes encoding insect-specific toxins from scorpions or spiders, by exchanging genes among different baculoviruses or by reorganizing the genome. The stability of baculoviruses in pesticide formulations can be further improved by adding new and more effective additives. Nonetheless, baculoviruses have a promising future as biopesticides, and can be successfully implemented in integrated pest management strategies.

Glossary

Budded virus (BV) The type of baculovirus virion that is formed by budding from the plasma membrane of infected cells and mediates the systemic spread of infection in the infected insect.

Granulovirus (GV) A betabaculovirus, forming granular-shaped occlusion bodies containing only a single virion each.

Homologous repeat (hr) A DNA sequence that is typically comprised of a series of imperfect palindromes and repeated at various locations in a baculovirus genome. Baculovirus homologous repeats function as origins of DNA replication and as transcriptional enhancers.

Nucleocapsid (NC) Nucleoprotein helical structure forming the core of the enveloped baculovirus.

Nucleopolyhedrovirus (NPV) Indication used for all baculoviruses that form polyhedral-shaped occlusion

bodies (OBs) in the nucleus (compare granulovirus, GV, with granular OBs).

Occlusion body (OB) A typical polyhedral or granular-shaped structure made of a paracrystalline protein matrix in which the baculovirus ODVs are embedded and that is found in the nucleus of infected cells.

Occlusion derived virus (ODV) The type of baculovirus virion that is assembled in the nucleus and becomes embedded within the paracrystalline matrix of the occlusion body.

PIF proteins A conserved series of crucial *per os* infectivity factors encoded by baculovirus genomes and being specifically required for oral infection.

Polyhedrin The major occlusion body protein of nucleopolyhedroviruses.

Introduction

Baculoviruses are insect-infecting viruses characterized by rod-shaped, enveloped virions that are packaged in viral occlusion bodies (OBs). These OBs allow the virus to survive outside a host insect for long times. Baculoviruses replicate in the nucleus of infected cells and are further characterized by their double-stranded (ds), circular DNA genomes, ranging in size from 80 to 180 kbp. Historically, baculoviruses were divided based on their OB appearance into granuloviruses (GVs), with a single virion per granular-shaped OB, and nucleopolyhedroviruses (NPVs) with many virions per polyhedral-shaped OB. The family *Baculoviridae* is subdivided into four genera, Lepidopteran-infecting baculoviruses are classified in the genus *Alphabaculovirus* or *Betabaculovirus*, while the *Gammabaculovirus* and *Deltabaculovirus* genera encompass the hymenopteran and dipteran insect infecting baculoviruses, respectively. So far, only one deltabaculovirus is known, *Culex nigripalpus* (Cuni) NPV that infects mosquito larvae. The alphabaculoviruses, on the other hand, form the most widely studied group of baculoviruses, which is primarily due to the availability of permissive insect cell cultures for many of these viruses.

Autographa californica multiple nucleopolyhedrovirus (AcMNPV) represents the most in-depth analysed alphabaculovirus. Furthermore, AcMNPV and *Bombyx mori* (Bm) NPV are used as expression vectors to produce (therapeutic) proteins, sub-unit vaccines and virus-like particles in cultured insect cells or caterpillars. AcMNPV is also an important tool to produce viral vectors for gene therapy purposes, especially for recombinant Adeno-associated virus (AAV). In addition, AcMNPV is being used for mammalian cell transduction and research is ongoing to use AcMNPV in human medicine as a gene delivery vector. A number of alpha- and betabaculoviruses have been developed into bio-insecticides, while biocontrol programs based on gammabaculoviruses to control sawflies also exist. The remainder of this article will focus on viruses belonging to the genus *Alphabaculovirus*.

Infection Cycle

Two Virion Phenotypes

Two distinct types of virions are produced in the infection cycle of alphabaculoviruses: the budded virus (BV) and the occlusion-derived virus (ODV). The latter type is embedded in OBs. BVs represent the first phenotype to be produced by an infected cell. BVs consist of a single nucleocapsid surrounded by an envelope obtained by budding from the plasma membrane of the infected cell. As the infection progresses, ODVs are assembled in the nucleus of infected cells and acquire an envelope that is derived from the inner nuclear membrane. As a consequence of the different sources of the BV and ODV envelopes, they have a significantly different lipid and protein composition (see Fig. 1). Unlike the ODVs of the baculoviruses classified in the other taxa, the ODVs of alphabaculoviruses can contain single (S) or multiple (M) nucleocapsids (NCs) per virion, depending on virus species. The S and M designation (SNPV and MNPV; *e.g.*, AcMNPV) does not hold taxonomic significance above the species level but is in practice an easy indicator to discriminate virus isolates obtained from the same host, but that belong to different viral species.

Towards the end of the infection, the ODVs become occluded in a para-crystalline protein matrix to form OBs that accumulate in the nucleus of the infected cell. OBs represent a feature that is common to all the currently classified baculoviruses, but the shape and size of the OBs depends on the virus isolate. The AcMNPV OBs are approximately 10 µm in diameter and are clearly visible using a light microscope. In NPVs these OBs have polyhedral shapes, hence the historical name “nuclear polyhedrosis” for the observed pathology that gave the NPVs their name. The major component of the OBs of most baculoviruses is the OB matrix protein, polyhedrin, which forms the bulk of the para-crystalline array in which the ODVs are embedded. Betabaculoviruses have an evolutionarily related, though slightly different protein, called granulins. Mature OBs are surrounded by a carbohydrate layer known as the polyhedral envelope or calyx. The alphabaculovirus-specific phosphoprotein called PP34 or the polyhedral envelope protein, is the major protein associated with the calyx in this group of viruses. The OBs of an AcMNPV *pp34* deletion mutant were found to have an increased sensitivity to alkaline disruption and an enhanced virulence in fourth instar *Spodoptera exigua* larvae, suggesting that the polyhedral calyx may stabilize the OBs in the environment. EM images of such a mutant showed OBs with a pitted appearance, apparently due to the loss of ODV particles.

Fig. 1 Schematic diagram of alphabaculovirus virion phenotypes showing BV and ODV structures. Components common to both virion phenotypes are shown in the center and components unique to each phenotype are indicated on the left and right. Note the BV glycoprotein spikes at both ends of the BV, as well as the ODV envelope proteins, which include a complex of *per os* infectivity factors (PIFs). PM = plasma membrane; INM = inner nuclear membrane. Adapted from Encyclopedia of Virology 3rd edition based on new insights (courtesy of D.A. Theilmann) and originally derived from Blissard, G.W., 1996. Cytotechnology 20, 73–93 with kind permission from Springer Science and Business Media.

Oral and Systemic Infection

The infection cycle is initiated when insects orally ingest OBs by consuming contaminated plant material. The OBs pass through the foregut, enter the midgut, and disassemble in response to the alkaline environment in there. This process releases the ODVs, which then traverse the peritrophic membrane (a protein–chitin structure that lines the gut) in order to infect the columnar epithelial cells of the lepidopteran midgut. This infection process may be aided by metalloproteases called enhancins, which degrade the peritrophic membrane and are encoded by certain alpha- and most betabaculoviruses. The ODVs bind to microvilli on the surface of midgut epithelial cells and are believed to enter the cells by direct fusion of the ODV envelope with the plasma membrane. A set of ten baculovirus *per os* infectivity factors (PIF proteins), embedded in the ODV envelope, is essential for oral infectivity and is involved in binding and fusion. Upon entry into the midgut epithelial cell, the NCs are released and transported along actin filaments to the nucleus, where transcription of viral genes is initiated.

Viral DNA replication and NC assembly occur within the nucleus in a viral structure known as the virogenic stroma (see Fig. 2). After an initial round of replication in the gut, BVs are produced at the basal side of the columnar cells and these BVs spread the infection systemically to the other tissues. BVs carry a viral fusion protein in their envelope allowing them to enter host cells by endocytosis. A recent study showed that internalization of AcMNPV BVs is facilitated by actin polymerization and dynamin. Microtubules, on the other hand, are involved in intracellular transport of BV-loaded endosomes. While still in an early endosomal stage, the viral envelope fuses with the endosomal envelope, releasing the NCs into the cytoplasm. These NCs then move to the nucleus along actin filaments. Most cells and tissues of the host insect are permissive for infection by BVs. These secondary infected cells first start to produce more BVs, and subsequently also start to produce ODVs and OBs.

Dissemination of OBs

Finally, the nuclei of the infected host cells will be filled with OBs. At least two viral enzymes, chitinase and cathepsin, assist in the release of OBs into the environment in a process called liquefaction: the disruption of infected cells and tissues by the breakdown of chitin and proteins, respectively. A third protein, called P10, helps to disintegrate the infected cell nuclei, thereby further dispersing individual OBs. The OBs released into the environment can remain stable for years and remain infectious if protected from ultraviolet light. The spread of OBs into the environment is probably aided by viral modification of host behaviour. Many alphabaculovirus-infected caterpillars show pre-death climbing behaviour (Wipfelkrankheit) and finally can be found hanging from the upper segments of the plants on which they fed. Release of the OBs at such elevated locations is believed to enhance transmission by contaminating the lower regions of the plant. Up in the plants, the infected caterpillars are also an easier prey for predating birds and these have been shown to aid in dispersal of OBs over large distances. In some baculovirus species, the *egt* gene, which encodes the enzyme ecdysteroid glucosyl transferase (EGT) that prevents larval moulting, is needed for pre-death climbing behaviour. In other species EGT is not required for climbing behaviour or rather plays an indirect role by prolonging the life span of infected caterpillars, thereby providing the time in which the caterpillars start to climb. The exact induction mechanism therefore remains unclear and most likely varies depending on the combination of virus and host species. In addition, it was shown that both AcMNPV and BmNPV induce hyperactivity in infected caterpillars for which the viral protein tyrosine phosphatase (PTP) is responsible, a protein specific for the clade of alphabaculoviruses to which these two viruses belong.

Genome Organization and Content

All baculoviruses have circular, double-stranded DNA genomes that are negatively supercoiled. The complete genomic sequences of over 200 alphabaculoviruses have been deposited to GenBank (NCBI). The smallest alphabaculovirus genome is that of *Maruca vitrata* (Mavi) NPV at 111,953 bp, while *Leucania separata* (Lese) NPV has with 168,041 bp the largest alphabaculovirus genome. The numbers of predicted genes with open reading frames (ORFs) of 50 amino acids or greater range from 126 (MaviNPV) to 169 (LeseNPV). The best studied alphabaculovirus, AcMNPV, has a genome size of 133,894 bp with 154 predicted genes and was the first baculovirus genome to be sequenced in its entirety. A distinct feature of nearly all baculoviruses is the presence of regions with homologous repeats (*hrs*) distributed over the genome. The *hr* regions contain a series of repeated palindromic sequences and can vary significantly in length. In the AcMNPV genome seven *hrs* are present, which contain repeats of an imperfect palindrome with a central EcoRI restriction site. Transient transcription and plasmid replication assays have shown for alphabaculoviruses that the *hr* sequences function as transcription enhancers and as replication origins. In addition, single copy *non-hr* replication origins have been identified in the genomes of AcMNPV, *Orgyia pseudotsugata* (Op) MNPV, and *Spodoptera exigua* (Se) MNPV.

Baculovirus genomes contain tightly packed ORFs with very short intergenic regions. Early and late genes are dispersed over the genome and both strands of the dsDNA genome carry approximately equal numbers of ORFs. Baculovirus genomes are relatively stable, but do display some plasticity, resulting in small variations in genome sequence when comparing virus isolates from the field. During evolution, recombination events and transposon insertions have led to the integration of new genes from co-infecting viruses or from the host insect. This resulted in sometimes extensive differences in gene content between baculoviruses belonging to different viral species. However, a set of 38 core genes is conserved in all sequenced baculoviruses (marked blue in Fig. 3) and as such, form the baculovirus genomic hall mark. The core genes are often involved in crucial processes in the viral replication cycle,

Fig. 2 Electron and light micrographs of baculovirus-infected insect cells. (a) An insect cell infected with AcMNPV showing the nuclear virogenic stroma (VS) that contains developing nucleocapsids and the OBs showing ODVs in the occlusion process (arrows). Scale = 1 μm . (b) An OB of the MNPV type, showing the process of occlusion of ODVs, containing multiple nucleocapsids in each virion. Many ODVs can be found in an OB. (c) A mature OB of the SNPV type, showing a single nucleocapsid in each virion (ODV) and many ODVs per occlusion body. Also note the formation of the polyhedral envelope (PE). (d) An NPV nucleocapsid budding from the plasma membrane (PM) of an infected cell. (e) Light microscopy of Tn5b1-4 cells infected with AcMNPV producing large relatively uniform OBs. such as midgut entry, DNA replication, transcription of viral genes and virion assembly. (For an overview table of the core genes please see the supplementary material). However, not all core genes are essential to allow the virus to infect a host; they may also play a role in virus fitness. On the other hand, genes that are not categorized as core genes may be crucial to the infection process for the viruses that carry these genes.

Phylogenetic analysis using the combined sequences of the core genes divides the baculoviruses in four major evolutionary clades and these correspond with the four genera in the family *Baculoviridae*, which were mentioned above (Fig. 4). Such a

Fig. 4 Neighbour-joining tree based on the amino acid alignment of 29 (of 38) core genes as identified in the first 29 sequenced baculovirus genomes. The alignment comprised 16349 positions. All branches have bootstrap values exceeding 50%. Bootstrap values > 95% are given along the branches. Adapted from Jehle, J.A., Blissard, G.W., Bonning, B.C., *et al.*, 2006. Archives of Virology 151, 1257–1266 with permission from Springer Nature Switzerland AG.

clades. Baculoviruses that lack particular orthologues of non-core genes may encode evolutionarily unrelated, but functionally similar proteins to be able to execute these crucial tasks. Functions of a number of genes important for alphabaculoviruses are described in the sections below.

Baculovirus Gene Expression

Temporal Regulation of Transcription

Baculovirus genes are expressed in a temporal cascade, beginning with immediate early and delayed early gene expression, which is followed by late and very late gene expression. After the initial uncoating of the viral genome in the nucleus, transcription of viral early genes is initiated by host RNA polymerase II, resulting in early transcription and the subsequent production of proteins associated with viral DNA replication and late gene expression. A variety of regulatory and even structural protein genes are also transcribed in the early phase. Production of early gene products results in the initiation of viral DNA replication, and the assembly and activity of a virus-encoded RNA polymerase. This viral RNA polymerase recognizes unique viral late promoters resulting in the transcription of genes encoding viral structural proteins as well as other late genes. Late gene transcription starts just prior to or concomitantly with the onset of DNA replication. Very late gene expression occurs at the terminal part of the replication cycle and includes the hyper-expressed viral genes *polh* and *p10*, encoding the major occlusion body protein polyhedrin and the 10K protein (P10) mentioned above that forms fibrillar structures in the nucleus and cytoplasm.

Early gene expression

Transfected purified baculovirus DNA is infectious, indicating that no viral proteins are required to initiate or mediate early transcription from the viral genome. Early viral gene expression is dependent though upon the host cell's RNA polymerase II complex and is sensitive to the drug α -amanitin. The early genes have been divided into two categories, immediate early (IE) and delayed early (DE) genes. IE genes require only cellular factors for expression whereas DE genes are either dependent on, or substantially upregulated by prior viral

Table 1 Conservation of non-core genes in lepidopteran baculoviruses^{a,b}

A. Genes conserved in all alpha- and betabaculoviruses	
<i>polh</i> (ac8) ^c	Occlusion body matrix, granulin in GVs
<i>bion</i> (ac13)	Baculovirus protein associated with inner and outer nuclear membrane (BION), involved in nuclear lipid accumulation
<i>f</i> protein gene (ac23) ^d	BV fusion protein (group II NPVs) or truncated homolog (group I NPVs)
<i>dbp</i> (ac25) ^e	DNA binding protein
<i>lef6</i> (ac28)	Unknown role in late gene transcription
<i>fgf</i> (ac32)	Fibroblast growth factor
<i>v-ubi</i> (ac35)	Ubiquitin-like protein
<i>pp31</i> (ac36)	PP31; phosphoprotein with ss DNA binding capacity
<i>lef11</i> (ac37)	Essential factor for DNA replication
<i>adprase</i> (ac38)	ADP-ribose pyrophosphatase (ADPRase).
<i>fp25</i> (ac61) ^e	Nuclear transport of ODV envelope proteins
<i>gp37</i> (ac64)	Fusolin-like protein, unclear function
<i>ac82</i>	Telokin-like protein
<i>p12</i> (ac102)	ODV-associated, nuclear localisation of G actin
<i>pif9</i> (ac108) ^e	Per os infectivity factor
<i>p24</i> (ac129)	Capsid protein
<i>pp34</i> (ac131) ^e	Polyhedral envelope-associated phosphoprotein (PEP)
<i>me53</i> (ac139)	NC associated protein that interacts with GP64 in virus budding
<i>ac145</i> ^e	Possible role in oral infectivity
<i>ac146</i>	Structural protein of BV and ODV
<i>ac75</i> ^e , <i>ac76</i> ^e , <i>ac106/107</i> ^e	Unknown function
B. Genes conserved in all alphabaculoviruses	
<i>orf1629</i> (ac9)	P78/83; Essential structural protein of the nucleocapsid
<i>egt</i> (ac15) ^e	Ecdysteroid UDP-glucosyltransferase, inhibits moulting
<i>pkip</i> (ac24)	Stimulates the activity of the viral protein kinase-1 in vitro
<i>ac51</i>	DNAJ domain protein, unknown function
<i>chaB</i> (ac60) ^e	Unknown function
<i>vp80</i> (ac104)	Essential structural protein of the nucleocapsid
<i>p10</i> (ac137) ^e	Major fibrillar structural protein, OB formation and dissemination
<i>exon0</i> (ac141) ^e	NC associated, BV nuclear egress
<i>ie0</i> (ac141 and ac147)	Transcriptional trans-activator, DNA replication
<i>ie1</i> (ac147) ^e	Transcriptional trans-activator, DNA replication
<i>ac18</i> , <i>ac102</i> ^e	Unknown functions
C. Genes conserved in group I and in almost all group II alphabaculoviruses	
<i>arif1</i> (ac20/21)	Rearrangement of cellular actin
<i>odv-e66</i> (ac46) ^f	ODV-E66
<i>lef10</i> (ac53a) ^f	Late essential factor 10
<i>iap2</i> (ac71)/ <i>iap3</i>	RING domain protein-possible apoptosis inhibition
<i>gp16</i> (ac130)	Unknown function
<i>p26</i> (ac136)	Unknown function
<i>ac17</i> , <i>ac19</i> , <i>ac26</i> , <i>ac29</i> ^d , <i>ac43</i> , <i>ac55</i> , <i>ac56</i> , <i>ac58/59</i> , <i>ac120</i>	Unknown functions
D. Genes conserved in all group I alphabaculoviruses	
<i>ptp</i> (ac1)	Protein tyrosine phosphatase, OB formation, behavioural manipulation
<i>bv-odve26</i> (ac16)	BV and ODV envelope associated protein
<i>iap1</i> (ac27)	RING domain protein-possible apoptosis inhibition
<i>gta</i> (ac42)	Global trans-activator-like protein
<i>ac44</i> ^g	Homolog of ascovirus iap/RING finger protein
<i>gp64</i> (ac128)	BV specific glycoprotein required for virion entry and budding
<i>lef7</i> (ac125) ^g	Late gene expression, role in DNA replication
<i>ie2</i> (ac151)	RING finger domain protein, transcriptional activation
<i>pe38</i> (ac153) ^g	RING domain protein, transcriptional activation
<i>ac4</i> ^h , <i>ac14</i> ^h , <i>ac30</i> , <i>ac73</i> , <i>ac74</i> ^h , <i>ac79</i> , <i>ac91</i> ^h , <i>ac111</i> ^h , <i>ac114</i> , <i>ac117</i> ^h , <i>ac124</i> , <i>ac132</i>	Unknown functions

gene expression. Early gene products are involved primarily in gene regulation, host modification, DNA replication, or are required for late gene expression. Many IE genes have a common motif, TATA-N_(24–26)CAGT, at their transcription start site. The promoters of IE and DE genes resemble typical eukaryotic RNA pol II promoters and contain host cell transcription factor binding sites.

The key viral regulatory proteins for early (and late) gene transcription are the immediate early proteins IE0 and IE1, encoded by the essential *ie0* gene complex. This *ie0* gene has two promoters and produces spliced and non-spliced transcripts. It is the only known baculovirus gene that produces two viral proteins via spliced transcripts, although several more baculovirus mRNAs are known to be generated through splicing. The IE0 protein contains the entire IE1 amino acid sequence, but in addition has an N-terminal extension that is variable in length depending on the viral species (54 amino acids in AcMNPV). Both the IE0 and IE1 proteins are present during the entire infection process due to the fact that the *ie0* transcript can also produce IE1, in addition to IE0, by internal translation initiation at the start codon of the *ie1* sequence. IE0 has peak expression prior to viral DNA replication, while IE1 becomes more abundant than IE0 when replication starts. IE1 levels continue to increase until the final stages of the infection. IE0 appears to be specific to alphabaculoviruses. IE0/1 is a typical acidic domain transcriptional trans-activator, similar to the herpesvirus VP16 protein, and activates viral gene transcription by both enhancer-dependent and independent mechanisms. Both proteins form dimers that bind to the genomic *hr* sequences, which serve as the transcriptional enhancers. IE0/1 is also essential for the viral replication complex, where it is believed to play the role of an origin binding protein. IE0 and IE1 can support viral DNA replication and BV production equally, but for some promoters (*lef4*, *lef6*, *ac79*, *p35*, *ac18*, *lef3*, *ac111*, and *39K*) IE0 is a more potent activator than IE1. This difference in potency is seen only when IE1/IE0 are expressed at relatively low levels, in line with the situation at early times post-infection. It has been suggested that IE0 expression in midgut cells may stimulate rapid DNA replication and BV production to allow the progeny virus to quickly escape the midgut and allow systemic dissemination of the infection.

Additional IE genes include the alphabaculovirus-specific *ie2* and *pe38* genes, which have been shown to augment viral transcription and, as indicated previously, viral DNA replication. Unlike *ie0/1*, both *ie2* and *pe38* can be deleted without interfering with the capacity to replicate. For viruses with *ie2* or *pe38* gene deletions, however, BV production and viral DNA replication are less efficient. Some of the most highly expressed viral IE genes are *he65* and *me53*. The presence of G-actin within the nucleus upon infection has been shown to be in part due to the function of HE65, whereas ME53 is needed for optimal virus production and in infected cells is associated with GP64 at foci thought to be budding sites. Overall, IE genes play crucial regulatory roles that coordinate the infection cycle. The *gp64* gene, encoding the AcMNPV BV fusion protein, is transcribed early in infection by host factors, but also has a late promoter element.

DE gene expression requires other viral factors, such as IE0/IE1 to achieve above basal levels of expression. An example of a DE promoter is the AcMNPV *pp31* promoter, which contains a TATA-CAGT sequence at the transcription start site and is dependent on IE1 for activated transcription. Also, the above-mentioned genes *lef4*, *lef6*, *ac79*, *p35*, *ac18*, *lef3*, *ac111*, and *39K* belong to the DE genes. In general, DE gene products are required for DNA replication and/or late gene expression.

Late and very late gene expression

Baculovirus late genes are transcribed by a viral-encoded DNA-dependent α -amanitin-insensitive RNA polymerase that recognizes baculovirus late promoters. Studies of the purified NPV RNA polymerase have shown that it is comprised of four major proteins, LEF4, LEF8, LEF9, and P47. Homologs of the corresponding genes have been identified in all baculovirus genomes sequenced to date. LEF4 has been shown to have enzymatic activity for RNA capping, and LEF8 and LEF9 contain conserved motifs found in other RNA polymerases. With only very rare exceptions, the baculovirus late promoters recognised by this viral RNA polymerase contain the sequence TAAG and transcriptome analysis has shown that the 5' end of late transcripts corresponds with the second position of this motif. In model late promoters that have been examined, only very short sequences immediately up- and downstream of the TAAG sequence were identified as components of the late promoter. Regions farther downstream have been shown to affect levels of very late gene expression.

Using transient assays, twenty AcMNPV genes were identified as important or necessary for late gene expression: the late expression factor genes (*lef1* to *lef12*), *pp31*, *p47*, *DNApol*, *vlf1*, *helicase*, *p35*, *ie1/0*, and *ie2*. Many of the *lef* genes are required for DNA replication, a prerequisite for late gene expression (see below). Typical examples of late genes are those encoding the structural proteins of the nucleocapsids and the envelope proteins of BVs and ODVs. Both *gp64* and *me53* have an early and a late gene promoter, allowing expression in both phases.

At very late times post infection, transcription of the two hyper-expressed late genes (*polh* and *p10*) is upregulated, resulting in accumulation of the polyhedrin and P10 proteins to extremely high levels. The burst of very late gene transcription is mediated by the late viral factor 1 (VLF1), which binds to an A/T-rich region, called a burst sequence, located downstream of the DTAAG motif in the *polh* and *p10* promoter regions. The hyper-expression of these two genes during the very late phase forms the basis of the baculovirus expression system. This recombinant protein production platform makes use of the promoters of either or both of these genes to efficiently express heterologous genes of interest in cultured insect cells.

Viral DNA Replication

Baculovirus DNA replication occurs in the nuclei of infected cells and is first detected 6–8 h post-infection of cultured *Spodoptera frugiperda* cells with AcMNPV and reaches top levels at 16–18 h post-infection. Several viral proteins have been shown to be crucial for AcMNPV DNA replication. These include DNA polymerase, the helicase P143 and several LEF proteins (LEF1; LEF2; LEF3,

LEF11). LEF1 and LEF2 mutually interact and possess primase activity. LEF3 is a single-stranded DNA binding protein that forms a complex with P143. Chemical cross-linking experiments showed that the viral trans-activator IE1 interacts with this complex. As shown in transient assays and by using mutant viruses, IE0 or IE1 can each support viral DNA replication, but both proteins are required to achieve full levels of viral replication. IE1 and presumably IE0 bind *hr* sequences in the baculovirus genome and therefore may function as origin-activating proteins. ME53 is a protein with two zinc-finger motifs, but its exact role in virus production is not clear. The exact role of LEF11 also remains enigmatic.

LEF7 is an F-box protein that is required for optimal levels of DNA replication in AcMNPV. Despite its important role in DNA replication, the *lef7* gene is conserved in the genomes of group I and a limited number of group II alpha- and betabaculoviruses. A number of other viral proteins have been shown to augment viral DNA replication in AcMNPV without being absolutely essential. These include the anti-apoptotic protein P35, the Inhibitor of apoptosis protein 1 (IAP1) and the group I alphabaculovirus-specific proteins IE2 and PE38. All three of IAP1, IE2 and PE38 are RING domain proteins. Both IE2 and PE38 are transcriptional activators (see above) and have ubiquitin ligase activities. However, it is not known whether this enzymatic function plays a role in DNA replication.

The mechanism by which the baculoviral genome replicates is not exactly known, but high molecular mass viral DNA molecules that are suggestive of genomic concatemers have been reported in infected cells. It has therefore been suggested that baculovirus DNA may replicate following a rolling circle model. More recently, it has been proposed that baculoviruses may use a recombination-dependent mechanism of viral DNA replication. In reality, it may even be a combination of the two, where recombination is used to resolve the concatemeric products of the rolling circle process. A protein that plays a role in producing genome length DNA molecules is Alkaline nuclease (AN). Alkaline nuclease family members repair dsDNA breaks and are involved in homologous recombination. The baculovirus AN may, therefore, be required in DNA processing, before the progeny genomes are packaged into the nucleocapsids. The ss-DNA binding protein LEF3 associates with AN, and this complex may play a crucial role in resolving replicative intermediates. Another protein that might be involved in this process is DBP (DNA binding protein), a protein that protects DNA against nuclease activity.

Virion Morphogenesis and Protein Composition

Nucleocapsids

The baculovirus life cycle is biphasic and produces two virion phenotypes, BV and ODV. NCs of both virion phenotypes are structurally identical. The NCs are rod-shaped, and measure approximately 30–60 nm by 250–300 nm. The NCs have characteristic cap and base structures (see Fig. 1) and several viral proteins are particularly associated with either of these two structures. NCs assemble in the ring zone of the nuclear virogenic stroma. In this process the viral dsDNA genome is densely packed within the NC in a spiral fashion. The small highly basic protein P6.9 is directly associated with the viral DNA and contains ca. 40% of arginine and 30% of serine/threonine residues. The highly basic nature of this protein functions in neutralizing the positive charges of the nucleic acid and aids in the condensation and packaging of the viral DNA. The condensed viral DNA is coated with the major capsid protein VP39. Recently, it was found that the 38K protein is crucial for the dephosphorylation of p6.9 during NC assembly. In contrast, uncoating of the viral DNA upon entry into the nucleus involves phosphorylation of p6.9.

Other AcMNPV proteins associated with the NCs include: P24, VP80, VP1054, BV/ODV-C42, P95, ORF1629, and EXON0 (AC141), AC142 and VLF1, and for several of these proteins more information about their function is available. AC142 is an essential gene required for NC formation. ORF1629 encodes the essential phosphoprotein P78/P83 that is associated with the basal end of the NC and needed for NC transport towards the nucleus. Deletion of BV/ODV-C42, VP80, VP1054, p6.9 and P95 showed that these genes are also essential for NC/BV assembly. In addition, P95 also has a domain required for oral infectivity of ODVs. VP80 and EXON0 are required for efficient egress of NCs (see also next section). Immunogold labelling has shown that VP80 binds to one end of the NCs (although it is not yet clear which end). VP80 also has DNA binding affinity, which may explain why VP80 deletion mutants do not assemble properly. Interestingly, the very late gene transcription factor VLF1 is also required for proper NC assembly and like VP80, typically associated with one end of the NCs. Q-PCR analysis showed that deletion of either the *vp80* or *vlf1* gene did not lower the levels of viral DNA produced. VLF1 is also not required for the production of genome-size DNA molecules, as previously suggested. Another NC-associated protein, VP1054, shares characteristics with the cellular DNA binding protein PUR α , and like this cellular protein, VP1054 has affinity for GGN-repeat motifs in DNA and RNA. GGN-repeat islands appear to be conserved in baculovirus genomes. A long (GGN)_n stretch is for instance present in AcMNPV on the complementary strand of *orf1629*, in which a CCN-repeat corresponds to a proline-rich domain in the essential protein P73/P87. As such, VP1054 might play a role in DNA packaging. Testing this hypothesis is rather difficult though, as artificial mutation of the GGN repeats will directly interfere with the function of P78/83 encoded on the complementary strand.

BV Morphogenesis

After their assembly in the virogenic stroma, NCs move along virus-induced, nuclear actin filaments to the nuclear periphery. The interaction with these actin filaments requires the NC protein VP80 that contains paramyosin-like domains. The NCs are believed to acquire an initial envelope when they egress from the nucleus to the cytoplasm to become BVs. By an unknown mechanism, the

initial envelope is lost and NCs are further transported to the cell surface, most likely utilizing microtubules. The AcMNPV protein EXON0 (AC141) seems to play a crucial role here, as it is found to co-purify with beta-tubulin and to bind to kinesin-1. Deletion of the *exon0* gene strongly reduced BV formation. At the cell surface, the NCs bud from the modified plasma membrane and as a consequence acquire an envelope carrying viral-encoded glycoproteins. Typical for the BV envelope of group I alphabaculoviruses is the presence of the major envelope glycoprotein GP64, which is a class III envelope fusion protein. GP64 is not present in ODVs and is therefore a BV-specific protein. Group II NPVs, GVs and deltabaculoviruses carry a functional equivalent, the F protein, which is a class I envelope fusion protein. Gammabaculoviruses do not have a BV fusion protein and as a consequence do not produce BVs, and, hence, are gut restricted.

GP64 glycoprotein characteristics

GP64 proteins are highly conserved, with approximately 80% amino acid sequence identity among all GP64 protein ectodomains examined. As indicated above, GP64 is structurally a class III glycoprotein that is phosphorylated, palmitoylated, and heavily glycosylated. It is found on the cell surface of infected cells and on the virion as a disulphide-linked trimer of GP64 monomers. GP64 functions in both viral entry and exit. In viral entry, GP64 is important for host cell binding and membrane fusion. Little is known of the details of GP64 interactions with host cell receptor(s) and the molecules that can serve as the host cell receptor for BV binding also remain unknown. However, GP64 binding appears to be highly promiscuous and this feature has been exploited for instance in the use of AcMNPV as a transduction vector for mammalian cells and in the use of GP64 for pseudo-typing retrovirus-based gene therapy vectors. The GP64 protein has also been used for peptide display on BV particles *e.g.*, for immunization purposes or drug screening.

After host cell binding mediated by GP64, the BVs are internalized via endocytosis and the low pH of the endosome triggers a conformational change in the GP64 trimers, resulting in activation of membrane fusion. Studies of GP64-mediated membrane fusion have indicated that large short-lived complexes of approximately 10 or more GP64 trimers form immediately prior to membrane fusion and are likely the unit structure of the membrane fusion mechanism. In addition, the opening of the fusion pore occurs rapidly after low pH triggering. Unlike F and many other membrane fusion proteins, the GP64 protein does not require a prior internal cleavage for maturation or activation of its fusogenic capacity.

Studies of a *gp64* gene knockout virus showed that GP64 is also necessary for efficient budding of progeny BVs. Because GP64 is found on the surface of infected cells, concentrated in discrete areas, it is thought that these concentrations of GP64 represent the sites of virion budding. ME53 co-localizes with the envelope glycoprotein GP64 in the same plasma membrane foci and does so in a GP64-dependent manner. ME-53 is encoded by all alphabaculovirus genomes and BV production is strongly attenuated in mutants lacking *me53*. Interestingly, ME53 is also found in association with isolated nucleocapsids and as such it may bridge the NCs with the GP64-containing envelope (possibly via the cytoplasmic tails of GP64) and by doing so assist in budding.

F protein properties

F proteins have been studied most extensively in SeMNPV (SE8), HearNPV (HA133), and LdMNPV (LD133). F proteins presumably serve a similar role in host receptor binding as GP64 although they appear to recognize a different host cell receptor. Both F and GP64 are glycosylated low-pH-activated membrane glycoproteins present as trimeric spikes in the BV envelope. F is a class I envelope fusion protein that becomes fusogenic after an internal cleavage by the cellular protease furin. This cleavage leads to the F1 and F2 components, which are interconnected by disulphide bonds. Unlike GP64, F proteins are not specific to BVs. Proteomic analyses of AcMNPV, HearNPV, ChchNPV and the deltabaculovirus CuniNPV have also identified F proteins in the ODVs. However, more detailed studies will be necessary to understand the potential role of the F protein in ODVs.

All viruses that encode a GP64 protein (group I alphabaculoviruses) also encode a homolog of the F protein (AC23 in AcMNPV, OP21 in OpMNPV). This F-homolog can be deleted with no substantial effect in cell culture infections as long as the *gp64* gene is intact. However, the conservation of *f* gene homologs in the genomes of the group I alphabaculoviruses suggests an important function and it was recently shown that deletion of the *ac23* from the AcMNPV genome results in delayed mortality of infected larvae. Thus, while F proteins found in group II alphabaculoviruses are essential entry proteins, the F homologs in group I are not essential, but appear to serve an accessory role that is important in the pathogenicity and/or virulence of the virus. Evolutionarily, the F protein is most likely the original baculovirus BV fusion protein as homologs of this protein are also encoded by insect genomes. An ancestor of the group I alphabaculoviruses has probably obtained a *gp64* gene by horizontal gene transfer, maybe from an insect retrovirus or via a retrotransposon, and the encoded GP64 protein has taken over the envelope fusion function in this clade of viruses.

Recent cryo-EM analysis of BV particles has shown that BVs are rather ovoid than rod-shaped (as obtained when using chemical fixation and as shown in previous drawings). Cryo-EM has also shown that both GP64 and F are found concentrated on both ends of the virion, although spikes are sometimes also found on the lateral sites of the ovoid (**Fig. 5**).

ODV Assembly and ODV Envelopes

Nucleocapsids destined to be incorporated into ODVs are retained in the nucleus and are enveloped by a lipid bilayer that is derived from the inner nuclear membrane. AcMNPV ORF142 and ODV-EC27 are essential for successful ODV assembly and for the production of infectious virus. ODV envelopes have been shown to contain a number of proteins that are not present in BVs (see **Fig. 1**). The most abundant AcMNPV ODV-envelope specific proteins include ODV-E18, ODV-E25, PIF5 (ODV-E56/ ODVP-6E), ODV-E66, and PIF0 (P74). In more recent years, additional ODV envelope proteins have been identified that are less

Fig. 5 Cryo-EM images of budded virus particles of group I and group II alphabaculoviruses. The ovoid BVs of AcMNPV (a) and SeMNPV (b) have an internal nucleocapsid (NC) surrounded by an envelope derived from the plasma membrane from which spikes (arrows) protrude at both ends. The spikes in AcMNPV are trimers of the envelope protein GP64, while SeMNPV has trimeric F protein spikes. Spikes might also be found along the lateral sides of the BVs. A pocket (P) of unknown composition is present between the lateral sites of the nucleocapsid and the envelope in these cryo-EM images. Scale bars represent 100 nm. The images are a courtesy of J.W.M. van Lent and have been published before as part of a larger figure in Wang, Q., Bosch, B.J., Vlak, J.M., *et al.*, 2016. Budded baculovirus particle structure revisited. *Journal of Invertebrate Pathology* 134, 15–22 and used with permission of Elsevier, Amsterdam, the Netherlands.

abundantly present but are absolutely required for oral infectivity. Therefore, they have been termed *per os* infectivity factors (PIFs). The previously discovered P74 and ODVE-56, and VP95 were subsequently renamed to PIF0, PIF5 and PIF8, respectively. With the recent discovery of PIF9 (AC108), ten PIFs have been allocated in total. Viruses with *pif* gene mutations are infectious by injection of their BVs into caterpillars, but do not show mortality upon oral infection with ODVs. The only exception is PIF8, which contains a DNA domain (NAE domain) which is required for BV formation. PIF8 is also associated with NCs, but the other PIFs are ODV-envelope specific. Most of the studies on PIF genes were done with AcMNPV or HearNPV.

PIF proteins, with the exception of PIF5, associate into a macromolecular protein complex, called the ODV entry complex. The macromolecular complex has a stable core consisting of PIF1–4. The other PIFs in the entry complex are associated with a relatively lower affinity to the core. One of the biological functions of the entry complex, apart from mediating midgut infection, is the protection of the individual PIF proteins against proteolytic degradation under alkaline circumstances. PIF proteins are highly specific and cannot easily be exchanged between viruses, possibly due to these complex protein-protein interactions in the ODV entry complex.

Tegument Proteins

GP41 is an ODV-specific glycoprotein encoded by a core gene. GP41 does not co-purify with either the NC or the envelope fraction and is therefore considered as a tegument protein, located in between the NC and envelope. A temperature-sensitive mutant of AcMNPV with a codon replacement in the *gp41* gene, showed that GP41 plays a critical role in virus assembly. When grown at the non-permissive temperature, the *gp41* ts mutants failed to produce ODVs and OBs, and, in addition, NCs did not egress from the nucleus to form BVs. GP41 therefore appears to play a key role in the assembly of both virion phenotypes, even though it has been detected only in ODVs. Tegument proteins appear to be acquired within the nucleus, when the ODV NCs become enveloped. Since BVs do not contain GP41, it was suggested that proteins that loosely associate with the NCs in the nucleus, might be lost when these migrate from the nucleus to the cytoplasm to become BVs.

Classification

Bombyx mori bidensovirus (BmBDV) is one of the causative agents that causes fatal densovirus in the silkworm. The single-stranded DNA genome is similar to that in parvovirus densoviruses. BmBDV was previously known as *Bombyx mori* densovirus type 2 (BmDENV-2) and was previously assigned to the *Densovirinae* in the *Parvoviridae* family. However, unlike parvoviruses the BmBDV genome consists of two ssDNA segments in separate capsids and encodes DNA polymerase B. Considering these unusual properties, in the Eighth Report of the International Committee on Taxonomy of Viruses (ICTV), this virus was excluded from the family *Parvoviridae*. In 2012, BmBDV was assigned to the new, sole and type species *Bombyx mori bidensovirus* in the new genus *Bidensovirus* within the new family *Bidnaviridae*. BmBDV is currently the only virus that possesses a single stranded DNA that encodes for a DNA polymerase. Characterizing its basic biology is important for understanding this new virus family and we can expect that other bidnaviruses will be isolated and characterized in the future.

Genome Organization and Expression Strategy

BmBDV has two linear single-stranded DNA segments about 6.5 kb (viral DNA1, VD1) and 6 kb (viral DNA2, VD2) in size. The complementary strands of the genomic DNA, but probably also VD1 and VD2, are encapsidated separately. The genome compartmentalization of such a bipartite virus gives rise to an obvious cost, because the different viral particle types containing at least one copy of each segment have to co-infect the same host cell during primary and systemic infection. If the different particle types are present at the same frequency, this cost would be minimized, while deviations from a one to one ratio would increase the cost of genome multipartition. However, genome segments accumulate at different frequencies in BmBDV virions and in BmBDV-infected midguts. The copy number of short-segment VD2 is higher than that of long-segment VD1. Faba bean necrotic stunt virus (FBNSV, family *Nanoviridae*) has an even more complex genome composition of eight circular ssDNA molecules encapsidated in individual icosahedral particles. The various segments of FBNSV present very different frequencies within individual host plants and virus particles as well as aphid vectors.

Several BmBDV isolates were obtained from silkworm and genomes of three of them, Yamanashi isolate (Japan), Zhenjiang isolate (China), and Indian isolate, have been sequenced. Sequence analysis of cloned VD1 and VD2 demonstrates that they are different DNA molecules that share a common 3' terminal sequence of 53 nucleotides. Both DNAs contain complementary terminal repeats in which the characteristic terminal palindrome observed in parvoviruses are not found (Fig. 1). The genomic structure of VD1 is similar to the self-synthesizing DNA transposons (hypothetical viruses termed polintovirus) characterized by terminal-inverted repeats and a unique set of proteins such as protein-primed DNA polymerase B (PolB) and ATPase. VD1 encodes four genes, *ns2*, *ns1*, and *vp* located on the 5'-half of one strand and *polB* on the 5'-half of the complementary strand. *ns2* and *ns1* consist of 381 and 951 nts respectively, and there is a 218 nts overlap between them. *vp* and *polB* consist of 1500 nts and 3318 nts respectively. There is an 8 nts overlap between *ns1* and *vp*. VD2 contains two genes which are located on the 5'-half of the complementary strands respectively, the *ns3* gene consists of 669 nts and the *p133* gene consists of 3483 nts. The conserved initiator elements TATA box and CAGT box, and the polyadenylation signal were found in the upstream and downstream regions of these genes respectively. Between the Zhenjiang isolate and Yamanashi isolate of BmBDV, VD1 shares 98.4% identity and VD2 shares 97.7% identity.

Transcript mapping shows that three mRNA molecules with sizes of 1.1, 1.5, and 3.3 kb respectively are expressed during transcription of VD1 of BmBDV. The 1.1 kb transcript corresponds to *ns2* and *ns1*. Further studies suggest that *ns2* and *ns1* are controlled by overlapping promoters, P5 and P5.5, respectively. Transcriptional start sites of *ns2* and *ns1* are located 21 nts upstream and 3 nts downstream of the *ns2* initiation codon, respectively. Transcription of *ns2* and *ns1* terminate at the same site. The 1.5 kb transcript derived from *vp*, starts at 57 nts upstream of the initiation codon and terminates 22 nts downstream of the terminal codon. The major structural protein VPs are synthesized by a leaky scanning mechanism from this mRNA. The 3.3 kb transcript corresponding to *polB*, transcribes from 22 nts upstream of the start codon and stops 13 nts after the terminal codon. Sequence analysis showed conserved initiator elements, a TATA box and a CAGT box, which were observed in the upstream regions of the viral genes. The activity of promoter P5 was investigated using luciferase reporter assay and the core elements of P5 were determined by a series of truncation mutants. The results suggest that P5 can drive reporter expression *in vitro*, and the TATA box, CAGT box and the upstream nt-205 to nt-236 region are important for the promoter activity. In VD2, the transcription of *ns3* initiates 29 nts upstream of the first ATG and terminates at the 59 nts downstream of the stop codon. The transcriptional initiation site and terminal site of *p133* are located at nt 5367 and nt 1771 of VD2, respectively. Alternative splicing of mRNA, which is common in parvoviruses, is not observed in BmBDV.

Pathology of Silkworm Associated With BmBDV

BmBDV replicates predominantly in the nuclei of columnar cells of the larval midgut epithelium, and leads to fatal densovirus in the silkworm. Symptoms of BmBDV-infected silkworm larvae include anorexia, diarrhea, and flaccidity. In diseased larvae, the

Fig. 1 Transcription map of BmBDV Zhenjiang isolate. The viral genome segments (VD1 and VD2) are depicted, flanked by terminal repeats (ITR), including the viral promoters (P5/5.5, P21, P97, P10 and P89). The viral mRNAs, transcription initiation and termination sites, and the proteins that they encode are shown. Polyadenylation is shown by a squiggly line. The open reading frames (ORFs) used to encode the viral proteins are shown.

color of the postero-midgut changed to pale yellow. Silkworms infected by BmBDV before the first day of the 4th instar discharged bead-like frass. Virus infection caused slow growth and extension of lengths of instar times. Different development stages of the silkworm larvae have different sensitivities to infection by BmBDV. The LT_{50} of first stage larvae is about 21 days, indicating that BmBDV has a long pathogenic process. BmBDV-infected 5th instar larvae could develop to the adult stage and produce the next generation, but the weight and survival rate of the pupa and the cocoon production decreases slightly. The main lesions occur in the nuclei of infected cells. Because of the accumulation of viral DNA, the nuclei of virus-infected cells become hypertrophied and stain intensely with methyl green or Feulgen reagent or exhibited an orange yellow or red fluorescence after staining with acridine orange at acidic pH. The hypertrophied nuclei of infected cells is 2.5 times larger than that of the normal cell and a voluminous dense homogeneous structure appeared in each of the infected nuclei at the late stage of infection. Infected columnar cells eventually degenerate and are discharged into the gut lumen, after which the mature virions in the degenerated infected cells were excreted along with the frass. However, cells of the midgut epithelium infected by BmBDV are not as readily discharged as those from larvae infected by *Bombyx mori* densovirus (BmDENV). This was consistent with the fact that BmBDV infection was chronic, while BmDENV caused acute disease. Two non-viral 45.5 kDa and 44 kDa proteins accumulate in BmBDV-infected degenerated cells in the midgut epithelium of the silkworm, and this accumulation is inversely correlated with that of viral structural proteins. TUNEL staining showed the accumulation of these proteins in degenerated cells infected by BmBDV was not due to apoptosis. Pathological changes are also observed in the goblet cells of infected midgut epithelium at the late stages of infection. Although the nuclei of goblet cells were infected and degenerated, the extent of damage was far less than that of columnar cells.

The ultrastructural changes in cells infected by BmBDV were observed both in the cytoplasm and the nucleus. In the cytoplasm, vesicles or cisternae near the granular endoplasmic reticulum, in which small spherical particles accumulated, could be observed, indicating the accumulation and transport of viral protein to the nucleus. During the replication of the virus, cellular organelles such as mitochondria and endoplasmic reticulum become vacuolized and degenerated. Meanwhile, a great many lysosomes and a large autophagosome containing degenerated organelles emerged. In the nucleus, the heterochromatin becomes very condensed and discrete. Hypertrophy of the virus-infected nucleus follows infection and a virogenic stroma appears. The virogenic stroma is less electron-dense than the surrounding nuclear matrix and occupies most of the nucleus. Simultaneously, the fibrillar and granular components of the nucleolus are segregated, and the hypertrophied nucleolus is pushed to the nuclear periphery. Electron-dense discrete sites of replication within the virogenic stroma appear early in infection. Following the multiplication of

the virus, these discrete sites in which virions were assembled increase in size. At the end of infection, the greatly enlarged nuclei are filled with thousands of small spherical virions, 20–24 nm in diameter. The virions enter the cytoplasm through the enlarged nucleopores or by destruction of the nuclear envelope. The complete virions are then liberated into the gut lumen along with the degenerated cells.

Viral Non-Structural Proteins

The BmBDV virus non-structural (NS) proteins are likely essential for viral replication as they are in parvoviruses. Bidensoviruses encode the DNA polymerase PolB which clusters with the DNA pol of polintoviruses. NS1 of BmBDV shows homology to that of densovirus and could be involved in the replication of the virus. A superfamily 3 helicase motif, which is conserved in NS1 of parvoviruses, was identified in the BmBDV NS1. However, another conserved initiator (replicator) motif in parvoviruses was lacking in BmBDV NS1. In parvoviruses, NS1 possesses multiple functions such as sequence specific DNA-binding, as well as helicase, ATP-dependent site-specific endonuclease and ATPase activities, involved in viral DNA replication. The NS1 of BmBDV also exhibits DNA binding, ATPase as well as helicase activities and NS1 interacted with the PolB. These facts implied that BmBDV NS1 is also a multifunctional protein, which possibly plays an important role in virus replication. BmBDV NS1 is a phosphorylated protein and the phosphorylation regulates its ATPase activity.

The *ns3* gene encodes a 27 kDa protein named NS3. Bioinformatics analysis suggests that NS3 possesses two zinc-finger motifs, 6 putative N glycosylation sites, and 4 putative phosphorylation sites. Homologs of BmBDV NS3 have also been identified in some densoviruses and baculoviruses. The homolog of NS3 in *Junonia coenia* densovirus is absolutely required for viral DNA replication, implying that BmBDV NS3 might play a similar and important role in the BmBDV viral life cycle. The NS3-like proteins from diverse viruses share a conserved Zn-finger motif. Inhibitors of apoptosis (IAP proteins) in baculoviruses also have Zn-finger motifs. It was hypothesized that NS3-like proteins might represent a novel family of apoptosis inhibitors in arthropod-infecting viruses.

NS2 was identified from BmBDV-infected silkworm midguts via comparative proteomics but this protein was not detected in virions, indicating this protein is a non-structural protein. NS2 of BmBDV shares no homology with other NS2 from parvoviruses and little is known about it. NS2 shares slight sequence similarity with some chromosomal replication initiator protein *dnaA* and DNA-binding response regulator. In virus-infected larvae, the transcription of the *ns2* gene was first detected 28 h post inoculation in low amounts, but in higher amounts at late stages of infection. Immunofluorescence showed NS2 ultimately concentrated on the nuclear membrane in BmN cells at late stages. Like the NS2, adenovirus death protein (ADP) is an Asn-glycosylated integral membrane protein which ultimately localizes to the nuclear membrane, and it is expressed early but is greatly amplified at late stages of infection. As ADP is required for efficient cell lysis and virus release, BmBDV NS2 might have the same function in facilitating the cell's lysis and virus release. As yet, the function of NS2 is still obscure.

Viral Structural Protein

Similar to parvoviruses, bidensoviruses are non-enveloped small spherical viruses with a diameter of 20 – 24 nm with equiaxial symmetry. However, the detailed ultrastructure of this virus remains to be elucidated. Viral structural proteins perform a wide variety of structural and biological functions during the virus life cycle, including host cell surface receptor recognition, pathogenicity determination, viral genomic encapsidation and host immune response detection and evasion.

BmBDV contains two genes *vp* and *p133* encoding the major capsid proteins (VPs) and minor capsid protein, respectively. Two VPs are produced by leaky scanning from the first and second ATG of *vp*. The VPs contain an N-terminal glycine-rich region as well as jelly-roll domains similar to parvovirus VPs. The conserved phospho-lipase A2 domain, which is essential for virus entry in parvoviruses, is not found in BmBDV. The BmBDV VPs expressed in a baculovirus expression system can auto-assemble into virus-like particles. *p133* encodes a 133 kDa protein named P133. Western blot analysis showed that the anti-P133 N-terminus and anti-P133 C-terminus serums recognized the same specific 133 kDa protein in virions, but no other proteins could be detected, suggesting that the *p133* gene encodes a single structural protein. Amino acid sequence alignment illustrated that the C-terminus is conserved between P133 and some viral structural proteins in family *Reoviridae* such as VP3 of cypovirus. In reoviruses, P133 homologs are located at the outer capsid shell and are involved in host recognition and virus entry. It appears most likely that P133 has a similar function. A 53 kDa protein was detected in purified virions using a specific antiserum against PolB, and three peptides with molecular masses of around 120, 70, and 53 kDa were also detected in virus-infected silkworm midgut, demonstrating that *polB* encodes a structural protein processed by post-translational cleavage.

Viral Replication

Unlike other ssDNA viruses, including parvoviruses, bidensoviruses encode the protein-primed DNA polymerase B rather than an endonuclease, indicating that bidensoviruses employ a different replication mechanism from that of parvoviruses. In fact, the replicative intermediates of viral DNAs similar to those of parvoviruses were not detected during virus infection, strongly suggesting that bidensovirus genomic DNAs does not replicate by a rolling circle mechanism, which is thought to be used by all

parvoviruses. However, details of the replication mechanisms of the bidensoviruses have not yet been defined. It is important to further characterize the viral specific DNA polymerase to understand the replication mechanism of bidensoviruses. Tijssen and Bergoin suggested that BmBDV DNA could replicate like the DNA of adenoviruses. In this model, the terminal protein (TP) which is covalently linked at the 5'-terminus of genome DNAs, serves as primers for viral DNA replication initiation. The terminal complementary repeats of bidensoviruses would form the panhandle structures, resulting in a double-stranded molecule that would then serve as a template for further replication of both minus and plus progeny strands. The 53 kDa peptide encoded by the *PolB* gene might be the TP of BmBDV, but the details of this peptide remain to be elucidated. Moreover, the terminus of BmBDV and polintovirus genomes start with the tetranucleotide GTGT/GTGT repeat, which is similar to the terminal GTAGTA sequence of adenovirus DNAs. The GTA at positions 4–6 of adenovirus DNA, rather than 1–3, are used as a template for pTP-CAT intermediate formation, and then, this intermediate jumps back to position 1 of the template to start elongation. This jumping-back mechanism ensures the integrity of the terminal sequences during replication of the linear genome.

Receptor-mediated attachment and entry are essential first steps in the virus life cycle. The interaction between the BmBDV attachment protein and its receptor is very specific. The silkworm *nsd-2* gene determines the resistance of silkworm to BmBDV. Its allele encodes a 12-pass transmembrane protein, +NSD2, which is homologous with amino acid transporter family and is expressed in predominantly the posterior part of the midgut. A deletion of 9 transmembrane domains of +NSD2 at the C-terminus results in resistance to BmBDV. +NSD-2 can interact with the VP of BmBDV *in vitro*. These facts suggest that +NSD-2 serves as a functional receptor for BmBDV and the target site recognized by the virus is present in the deleted portion of the membrane protein. However, the BmBDV genome can replicate at a low level and the virus VP can be detected before 48 h post-infection in resistant silkworm, indicating that +NSD-2 regulates virus replication in addition to its function as a cell receptor protein for BmBDV.

Virus Evolution

The linear single-stranded DNA genomic structure of bidensoviruses as well as the dimensions and morphology of the virions are like those of parvoviruses. Similar to the insect densovirus, BmBDV infection leads to a fatal densovirus. BmBDV NS1 is homologous to densovirus NS1, possessing a conservative superfamily 3 helicase domain. Although the major structural protein VP of BmBDV didn't share significant sequence similarity to that of parvoviruses, the BmBDV VP encompasses counterparts to all 8 β -strands that can form the core of the jelly-roll fold as parvoviruses, suggesting that VP was a homolog of the VP of parvoviruses. These features strongly suggest that bidnaviruses originated from a parvovirus ancestor. The main feature of bidensoviruses that differs from ssDNA viruses is that the VD1 of bidensoviruses encode the protein-primed DNA polymerase B. A phylogenetic tree indicates that the PolB of BmBDV was derived from polintovirus. In BmBDV VD2, *p133* encodes the 133 kDa minor structural protein (P133) that shares sequence similarity to structural proteins of some reoviruses. Phylogenetic analysis demonstrates that bidensoviruses cluster with members of the genus *Cypovirus*. The non-structural protein NS3 shows some homology with NS3 of some densovirus, and the homologs of NS3 were also found in some granuloviruses and nucleopolyhedroviruses. Phylogenetic analysis shows that BmBDV NS3 clusters with granuloviruses, suggesting that BmBDV most likely acquired the NS3 from a granulovirus rather than a densovirus. All together, it appears that bidnaviruses evolved from a parvovirus ancestor from which they inherited a jelly-roll capsid protein and a superfamily 3 helicase and that later, the genome of the ancestral parvovirus integrated into a polintovirus genome acquiring the polintovirus PolB gene along with terminal inverted repeats to generate the VD1 genome segment. It is possible that the VD2 segment of BmBDV evolved directly from the VD1 segment by replacement of the parvoviral and polintoviral genes with genes from reoviruses and baculoviruses.

Bunyaviruses of Arthropods (*Mypoviridae*, *Nairoviridae*, *Peribunyaviridae*, *Phasmaviridae*, *Phunuiviridae*, *Wupedeviridae*)

Sandra Junglen, Charité - University Medicine Berlin, Berlin, Germany

© 2021 Published by Elsevier Ltd.

Glossary

Ambisense Coding strategy used by some bunyaviruses in which a single stranded genome segment encodes proteins in both positive and negative sense orientations.

Arbovirus A virus transmitted to vertebrates by hematophagous (blood-feeding) insects.

Arthropod-specific virus A virus that infects only arthropods and cannot be transmitted to vertebrates.

Bunyavirus Any member of the order *Bunyavirales*.

Cap snatching Cleavage of the capped 5' end of a cellular mRNA to produce short oligonucleotides that are used to prime viral mRNA transcription. The cellular sequences are incorporated into the viral mRNAs.

Insect-specific virus A virus that infects only insects and cannot be transmitted to vertebrates.

Unclassified A virus not yet classified as a member of a taxon.

Introduction

At the time when Gouléako virus and Herbert virus as the first insect-specific bunyaviruses were discovered, bunyaviruses were organized as a family comprising the five genera *Phlebovirus*, *Orthobunyavirus*, *Hantavirus*, *Tospovirus* and *Nairovirus*. All bunyaviruses detected previously in blood-feeding arthropods were able to replicate in vertebrate cells and were considered to be arboviruses. The detection of bunyaviruses in mosquitoes that replicated efficiently in insect cells but were unable to infect vertebrate cells was a peculiar novelty. Moreover, these viruses did not group with any of the classical arthropod-associated bunyavirus genera (*Phlebovirus*, *Orthobunyavirus* and *Nairovirus*) and defined new deep rooting lineages in the bunyavirus phylogeny. Many other insect-specific bunyaviruses were discovered in subsequent years, giving rise to the reorganization of the family into an order comprising twelve families at present. [Table 1](#) gives an overview of selected classified arthropod-specific bunyaviruses. As most of these viruses were identified by metagenomic sequencing of pooled arthropod specimens and no virus isolates are available, the following paragraphs are limited to mainly those viruses for which the phenotypic and molecular characteristics have been determined.

Virion Structure

The morphology of virions has been analyzed for viruses of the genera *Herbevirus*, *Feravirus*, *Goukovirus*, *Phasivirus* and *Jonvirus*. Herbert virus (genus *Herbevirus*) and Badu virus (genus *Phasivirus*) particles are spherical, enveloped and 90–110 nm or 130 nm in diameter, respectively ([Fig. 1](#)). The enveloped virions of Gouléako virus (genus *Goukovirus*) and Ferak virus (genus *Feravirus*) are pleomorphic with a diameter of 70 – 120 nm. Jonchet virus (genus *Jonvirus*) has a unique morphology in the Order *Bunyavirales*. Jonchet virus has two types of enveloped virions with either a tubular morphology of about 60 nm up to 600 nm or a spherical morphology with a diameter of about 80 nm. The virions consist of four structural proteins, termed Gn, Gc, N, and L, in analogy to the bunyavirus terminology.

Genome and Coding Strategies of the Viral Genomes

The genomes consist of three single-stranded RNA segments of negative-sense or ambisense polarity. The segments are designated L (large), M (medium) and S (small) and have complementary terminal sequences that are conserved among viruses of the same genus and may also be conserved within the same family but differ between families. The terminal nucleotides have been identified for only the insect-specific bunyaviruses shown in [Table 2](#). The conserved terminal nucleotides of the 3'- and 5'-prime ends are complementary allowing the RNA segments to base-pair and form panhandle structures.

The complete genomes of all classified bunyaviruses have been sequenced. However, genome annotations are available for only those viruses that were isolated in cell culture and analyzed by molecular methods such as protein sequencing by mass spectrometry. The genome organization for those species is shown in [Fig. 2](#).

The L segment encodes the RNA-dependent RNA polymerase (RdRp) protein, also named L protein.

The M segment encodes the two glycoproteins which are translated as a precursor polypeptide (glycoprotein precursor, GPC) and posttranslationally cleaved into Gc and Gn. Viruses of the genera *Feravirus* and *Jonvirus* in the family *Phasmaviridae* encode an

additional non-structural protein named NSm. The NSm protein of Jonchet virus is encoded at the N-terminal part of the GPC protein and posttranslationally cleaved as observed in phleboviruses. In contrast the NSm protein of Ferak virus shows a unique coding strategy as the NSm is encoded in a second small ORF upstream of the GPC ORF that overlaps the N terminus of the GPC

**Fig. 2** Schematic coding strategy of selected arthropod-specific bunyaviruses. The viral RNA genome is shown as a black line with the length in nucleotides indicated above each segment. Viral mRNAs are represented as blue arrows with boxes indicating the host-derived primer sequences. Proteins are shown as green boxes with predicted protein sizes given in or beside the boxes.

ORF. The S segment encodes the N protein and in the case of fera- and jonviruses also a nonstructural protein, named NSs, in different overlapping reading frames in the complementary-sense RNA. The NSs ORF is located upstream of the N ORF. The two proteins are translated from the same mRNA species, the result of alternative initiation at different AUG codons. While Shuangou insect virus 1 (genus *Shangavirus*) lacks a NSs, it has been predicted to encode a NSm protein. All other arthropod-specific bunyaviruses seem not to encode NSm or NSs proteins which is in contrast to the vertebrate-infecting bunyaviruses that encode mostly those two proteins.

Goukoviruses contain the shortest bunyavirus genomes identified to date consisting of S, M and L segments of about 1.1, 3.2 and 6.4 kb, respectively.

The L protein of herbeviruses contains an additional region of about 150 amino acids and is thus longer than the related orthobunyaviruses. However, the glycoprotein precursor of herbeviruses is ca. 600 amino acids shorter compared to orthobunyaviruses as the variable region of the Gc protein as well as the NSm protein are lacking.

Viral Replication Cycle

Infection of the target cell is believed to be mediated by interaction of the glycoproteins with cellular receptors. However, no cellular receptors nor the role of each glycoprotein attachment and entry has been identified for any arthropod-specific bunyavirus.

Viral replication takes place in the cytoplasm. The negative-strand RNA is replicated via a complementary full-length positive-sense RNA. The mRNA contains a 5'-methylated capped nonviral (primer) sequence and is truncated at its 3'-end compared to the genomic full-length and is used for transcription and translation. Further analyses on Herbert virus, Gouléako virus, Jonchet virus and Ferak virus have shown that the 5'-nonvirally templated elements are obtained from host cell mRNAs by a cap-snatching mechanism that is mediated by an endonuclease activity of the viral L protein. The 3'-end of the mRNAs terminate ca. 100–200 nucleotides before the end of the genomic RNA. There is no apparent termination signal present. Transcription in arthropod-specific bunyaviruses is similar to that of the plant- and vertebrate-infecting bunyaviruses.

Assembly and release of bunyaviruses occurs at the Golgi complex. Similar observations have been made for Herbert virus. Two types of premature spherical viral particles of high and low electron densities, termed intracellular annular viruses (IAV) and intracellular dense viruses (IDV), were detected in Golgi vesicles. Maturation and budding of Herbert virions occurs at the Golgi membrane of Golgi vesicles filled with IAV and IDV.

Host Associations, Virus Maintenance Cycles and Pathogenicity

The progress in the area of metagenomic sequencing enabled the detection of bunyavirus-like sequences in a huge diversity of arthropods. For example, bunyavirus sequences were found in beetles, bees, dragonflies, moths, water striders, millipedes, spiders and springtails to name just a few, indicating that bunyaviruses have coevolved with their arthropod hosts. Despite the accumulation of sequence data from diverse arthropod hosts, there is little knowledge on the routes of transmission of these viruses and their pathogenicity in arthropod hosts.

Glossary

Dipteran A member of the insect order Diptera: true flies.

Hemipteran A member of the insect order Hemiptera: true bugs (including aphids).

Horizontal transmission Transmission from one individual to another in the same generation.

Hymenopteran A member of the insect order Hymenoptera: wasps and bees.

Intergenic region Region between the two open reading frames in the dicistrovirus genome.

Lepidopteran A member of the insect order Lepidoptera: moths and butterflies.

Orthopteran A member of the insect order Orthoptera: crickets and grasshoppers.

Pathogenicity The ability of a virus to cause damage and disease in a host.

Penaeid A shrimp from the family Penaeidae.

Polyprotein A protein that is cleaved after synthesis to produce a number of smaller functional proteins.

Vertical transmission Transmission of virus directly from an infected mother to her offspring.

Virion Infective form of a virus outside a host cell, consisting of a nucleic acid core and a protein coat.

VPg A virally encoded protein covalently linked to the 5' end of the viral genome.

Introduction

For years, viruses in the *Dicistroviridae* family had no definitive taxonomic placement and were referred to as “picorna-like” based simply on their similarities to mammalian picornaviruses possessing an RNA genome, the size of virions, the composition of capsids, and other biophysical characteristics. Genome sequencing revolutionized biological science across many fields including virus taxonomy. In 1998, the first complete genome sequence of an insect picorna-like virus, *Drosophila C virus* (DCV) was published and predicted to possess a genome organization different from that of mammalian picornaviruses. Unlike other picornaviruses with monopartite, monocistronic genomes, DCV has a monopartite bicistronic genome with replicase proteins encoded by a 5'-proximal ORF and capsid proteins encoded by a 3'-proximal ORF, which are separated by an intergenic region (IGR), suggesting this virus belongs to a previously undescribed virus family. Subsequently, the increasing availability of complete genome sequences of insect picorna-like viruses and phylogenetic data have confirmed the distinct genome architecture of the dicistroviruses, and have conclusively defined *Dicistroviridae*, a taxonomic designation which was officially adopted by the ICTV in 2002. The family currently includes fifteen members officially recognized by the ICTV and many additional unclassified species.

Taxonomy and Classification

The *Dicistroviridae* family is a member of the Order *Picornavirales* and currently comprises 15 species classified into three genera, *Aparavirus* (derived from acute bee paralysis virus), *Cripavirus* (derived from cricket paralysis virus), and *Triatovirus* (derived from *Triatoma* virus). There are several other potential candidates for the family but these have yet to be accepted as species by the ICTV. For the purposes of this article, we will limit our discussion to only those officially classified species shown in Table 1.

Biophysical Properties

Dicistrovirus virions are roughly spherical as observed by electron microscopy with a particle diameter of approximately 30 nm and no envelope (Fig. 1(a)). The virions are composed of 60 protomers, each comprised of a single molecule of each of the major capsid proteins VP1, VP2, and VP3 (Fig. 1(b)). The major capsid proteins VP1 to VP3 exhibit a jelly roll β -sandwich fold and form the capsid shell with pseudo- $T = 3$ icosahedral symmetry. A smaller protein, VP4, is also present inside the virion and in contact with the RNA genome. In Cricket paralysis virus (CrPV) and Israeli acute paralysis virus (IAPV), VP4 is located on the internal surface of the five-fold axis below VP1, but in contrast, is disordered in *Triatoma* virus (TrV). In most species, a protein precursor (VP0) is present which is cleaved to yield capsid proteins VP3 and VP4 during virion maturation. An Asp-Asp-Phe (DDF) motif, which is part of the VP1 subunit and conserved among dicistroviruses may be involved in VP0 cleavage. There are spike-like

Fig. 1 Virion structure. (a) Negative stained electron micrograph of CrPV virions that appear spherical in shape. (b) Schematic diagram of a dicistrovirus virion showing the surface packing of the coat proteins (VP1, VP2, and VP3) (courtesy of A. E. Mechaly, with permission). The comparison of surface structures of, from left to right, *Triatoma* virus, Israeli acute bee paralysis virus, and Cricket paralysis virus. Color scale indicates the distance from the particle center (Å). Protrusions are shown in red and depressions are shown in blue (courtesy of A. E. Mechaly, with permission). (a) Courtesy of Carl Reingannum, with permission.

protrusions that are formed by two antiparallel β -strands from the CD loop of VP3 and a C-terminal β -strand of VP1 on the surface of virions; however, the size of the protrusions varies among different dicistroviruses (Fig. 1(c)–(e)). Unlike many picornaviruses, some dicistroviruses such as Cricket paralysis virus (CrPV), Black queen cell virus (BQCV), and IAPV do not contain a hydrophobic pocket in capsid protein VP1, which is naturally occupied by a lipid and can be targeted by capsid-binding antiviral compounds.

Proteins account for 70% of virion weight. The approximately 200 kDa nonstructural polyprotein and 100 kDa structural polyprotein are encoded by ORF 1 and ORF 2, respectively. Virions contain three major structural (capsid) viral proteins, VP1, VP2, and VP3. The size of these capsid proteins ranges from 24 to 40 kDa; an exception is Taura syndrome virus (TSV), in which VP1 is 55 kDa. A fourth smaller capsid protein (VP4) of roughly 4.5–9 kDa has also been reported in some species.

Virions are stable in acidic conditions (to pH = 3.0) and resistant to detergents and organic solvents such as ether and chloroform. Mature virions have a buoyant density of 1.34–1.39 g ml⁻¹ in CsCl in the pH range of 7–9 and sedimentation coefficients of between 153 and 167 S. However, physicochemical properties have not been fully established for all members of the family. A summary of the biophysical properties of dicistrovirus virions is provided in Table 2.

Organization of the Dicistrovirus Genome

The positive-sense single-stranded RNA genomes of dicistroviruses are monopartite and dicistronic and approximately 8500–10,000 nt in size. The RNA genomes comprise two non-overlapping ORFs of approximately 5500 and 2600 nt that are separated by an untranslated intergenic region (IGR) of ~190 nt and flanked by 5' and 3' untranslated regions (UTRs) (Fig. 2). The length of the UTRs at each end of the genome varies. The 5'-proximal and 3'-proximal ORFs encode non-structural and structural protein precursors, respectively. Each ORF is preceded by a specific RNA structure identified as an internal ribosome entry site (IRES), which allows for the initiation of translation in a cap-independent manner. Components of the non-structural

^aMinor virion components are shown in brackets. These are presumed to be precursors of VP4–VP3.

Fig. 2 Organization of the dicistrovirus genome. The RNA genome contains two non-overlapping open reading frames (ORFs) separated by an intergenic region (IGR) and flanked by the 5' and 3' untranslated regions (UTRs). The 5' proximal ORF encodes the nonstructural proteins: RNA helicase (Hel), 2 x VPg, cysteine protease (Pro), and RNA-dependent RNA polymerase (RdRp). The 3'-proximal ORF encodes structural proteins: VP2, VP4, VP3, and VP1. The internal ribosome entry sites (IRESs) are located within the 5'-UTR and the IGR.

polyprotein include an RNA helicase (Hel), 3C-like cysteine protease (Pro), and RNA-dependent RNA polymerase (RdRp) lying in the order (5′–3′) Hel-Pro-RdRp. The structural proteins that build the capsid are arranged in the order of VP2-VP4-VP3-VP1. VP4 is cleaved from VP3 during the maturation of the virion. A small genome-linked virus protein (VPg), derived from ORF1, is covalently attached to the 5′ end of the genome and plays an important role in RNA replication. The VPg sequence is repeated in most dicistrovirus genomes with the number of repeats being species-dependent. The presence of multiple VPg copies is predicted to allow for multiple progeny RNA molecules to be produced per template. The poly(A) tail at the 3′ end of the genomes is presumed to function synergistically with the IRES to enhance IRES-mediated translation efficiency,

Virus Replication and Genome Expression

The ways in which the dicistrovirus viral capsid proteins interact with host cellular receptors to facilitate entry is not fully understood. Likely, however, dicistroviruses enter host cells via clathrin-mediated endocytosis. The recent development of infectious full-length clones of dicistroviruses will make the study of virus replication and genome expression possible. Dicistroviruses are considered to use the same general replication mechanisms common to picornaviruses. Following viral attachment to the host cell, conformational changes occur in the capsid facilitating genome release into the cytoplasm. The RNA genome is immediately translated into polyproteins. The multiplication of the viral genomic RNA involves the synthesis of a negative-strand RNA intermediate from the positive strand, which, in turn, serves as a template for the production of progeny positive-strand RNAs. The viral RNA-dependent RNA polymerase (RdRP) named 3Dpol is responsible for primarily RNA synthesis. The 3Dpol uses VPg (also called 3B) at the 5′ terminus of the genomic RNA as a primer to initiate the replication process. The first step in protein-primed initiation is the uridylation of a tyrosine residue at position 3 of VPg by the 3D viral polymerase. The resulting VPg-pUpU then serves as a primer for the synthesis of both negative as well as positive-strand RNA at the 3′- or 5′-end of the template genomes.

The viral genomic RNA also functions as mRNA which is translated into proteins for the production of new virion materials. The initiation of protein synthesis occurs immediately upon entry into the host cell and coincides with the shutdown or downregulation of host cell protein synthesis. For example, CrPV infection inhibits the host translational machinery, a process called host shutoff which is concomitant with an increase in CrPV viral protein synthesis. Translation of the dicistronic RNA genome of dicistroviruses proceeds directly from internal ribosome entry sites (IRESs) and RNA stem-loop structures located within the 5′-UTR and the IGR. Although the mechanism of IRES-directed translation initiation has not been fully defined and varies among different IRES elements, the IGR-IRES of dicistroviruses is one of the best-studied IRES elements. The IGR IRES can initiate translation without codon-anticodon base pairing between the initiation AUG codon and the initiator Met-tRNA. Moreover, the IGR IRES can directly recruit and bind the ribosome in the absence of canonical initiation factors. The activities of the IGR IRES depend on two conserved and independently folded domains that work in concert to mediate ribosome recruitment and direct translation initiation. In most cases, the initiation codon is CCU (Pro) while the first codon of VP2 encodes an alanine residue. It has been shown empirically that the glutamine at the 5′ end of PSIV VP2 can be replaced with any other amino acid to produce a mature protein in an in vitro translation system. Conversely, the 5′-UTR IRES is not well conserved within the group and there are no clear structural homologies between the 5′-UTR IRES and IGR IRES. Translation activity of the IGR IRES is relatively stronger than that of the 5′-UTR IRES. However, a study with CrPV showed that IGR IRES translational activity is coupled with 5′UTR IRES translational activity and the increased IGR IRES translation of capsid proteins is stimulated when the expression of non-structural proteins is active.

Host Range

To date, all members of the *Dicistroviridae* have been isolated from arthropods. Most dicistroviruses have a range of multiple hosts. The hymenopteran viruses, Acute bee paralysis virus (ABPV), Kashmir bee virus (KBV), IAPV, KBV, and BQCV which were originally identified in the European honey bee (*Apis mellifera*) have recently been detected in other bee species, which is likely due to the sharing of foraging sites as well as the high mutation rates of the RNA viruses in driving viral adaptation and host expansion. In addition, it is evident that these bee viruses are capable of replicating in the ectoparasitic mite *Varroa destructor*, which acts as a vector of viruses in honey bee colonies. Studies have shown that the host of predilection for *Solenopsis invicta* virus 1 is the red imported fire ant, *Solenopsis invicta*. However, in areas where *S. invicta* and the congener, *Solenopsis geminata* are sympatric, the virus will infect both species. SINV-1 has also been detected in the black imported fire ant, *S. richteri*.

Dicistroviruses found in Hemiptera (the combined orders of Heteroptera and Homoptera), also have multiple host ranges. *Rhopalosiphum padi* virus (RhPV) has been isolated from laboratory and field populations of the aphids *Rhopalosiphum padi*, *R. maidis*, *R. rufiabdominalis*, *Schizaphis graminum*, *Diuraphis noxia*, and *Metopolophium dirhodum*. Aphid lethal paralysis virus (ALPV) has been isolated from several species of aphids, including *R. padi*, *M. dirhodum*, and *Sitobion avenae*; more recently, it has been identified in the honey bee *A. mellifera*. The Himetobi P virus (HiPV) and *Plautia stali* intestine virus (PSIV) are found in true bugs rather than aphids with HiPV having been isolated from the leafhoppers *Laodelphax striatellus*, *Sogatella furcifera*, and *Nilaparvata lugens*, and PSIV from the brown-winged green bug, *Plautia stali*. TrV is also a virus of hemipterans and has been found in the hematophagous triatomine bug, *Triatoma infestans*, which is also a vector of the protozoan agent responsible for Chagas disease in South America.

DCV has a host range restricted to dipterans and has been isolated from *Drosophila melanogaster* and the sibling species *D. simulans*. Taura syndrome virus (TSV) is a virus of penaeid shrimps and has been isolated from a number of shrimp species including *Litopenaeus vannamei*, *L. stylirostris*, *Metapenaeus ensis*, and *Penaeus monodon*. *P. chinensis* is highly susceptible to infection in experimental bioassays. CrPV was originally isolated from the field crickets, *Teleogryllus oceanicus* and *T. commodus*. This virus has an exceptionally broad host range as it has subsequently been isolated from a further 20 species belonging to five taxonomic orders: Orthoptera, Hymenoptera, Lepidoptera, Hemiptera, and Diptera, as well as a range of cultured insect cells. CrPV is the only dicistrovirus isolated from lepidopterans – in fact from ten lepidopteran species.

All of the above records refer to the natural host range of the viruses. To a certain extent, studies on the experimental host range of dicistroviruses are limited and those that have been carried out have not substantially extended the known host ranges. Again the exceptions are CrPV and DCV. CrPV replicates in a number of established insect cell lines including those from *Drosophila*, the hemipteran *Agallia constricta*, and the lepidopterans *Pieris rapae*, *Plutella xylostella*, *Spodoptera ornithogalli*, and *Trichoplusia ni*. In addition to insect cell lines, CrPV has also been found to replicate readily in larvae of the greater waxmoth, *Galleria mellonella*. This is an easy insect to rear and maintain and virus yields can be very high. Apart from CrPV, the only other dicistrovirus shown to replicate in cultured cells is DCV, which multiplies in several *Drosophila* cell lines (some DCV isolates also replicate in the greater waxmoth). Reports that TSV can replicate in some mammalian cell lines have never been substantiated and may simply be attributable to the production of a cytopathic effect in the absence of virus replication.

Pathology and Transmission

Dicistroviruses are significant pathogens of agricultural and health importance. Dicistrovirus infections vary considerably in virulence and pathogenicity. While in some instances, dicistroviruses may not produce noticeable pathological symptoms, most dicistrovirus infections result in impaired functions, severe diseases, reduced life expectancy, and increased mortality in infected hosts. RNA interference (RNAi) is a major immune defense mechanism against viruses in arthropods. Viruses, in turn, have evolved to encode RNA silencing suppressor proteins to counterattack antiviral defense of hosts. The activity of the virus-encoded suppressors of host RNAi (VSRs) has been identified in dicistroviruses including DCV, CrPV, and IAPV. This evolutionary arms race between dicistroviruses and their hosts defines the pathogenicity of viruses in hosts.

Most of the dicistroviruses exhibit a tissue tropism toward some part of the alimentary canal, often replicating in epithelial cells of the gut and subsequently shedding virus particles into the gut lumen where the virus accumulates in the feces and serves as inoculum. DCV is a viral pathogen affecting the model organism, *D. melanogaster*, which has often been used for deciphering virus-host interactions. The DCV infection triggers a nutritional stress in infected flies, which is the result of intestinal obstruction; the virus displays an affinity for the food-storage organ of the digestive tract, the crop, in infected hosts. The related virus, CrPV, does not trigger the same pathology.

The hymenopteran viruses, ABPV, IAPV, KBV, and BQCV are highly pathogenic to the honey bee, *A. mellifera*. The viruses attack all developmental stages and castes of the honey bees and replicate in most tissues of infected bees, including the tissues of the gut, fat body, mandibular glands, hypopharyngeal glands, hemolymph, and nerve. ABPV and IAPV infections are associated with paralysis of adult bees, abnormal trembling of the wings and body, flightlessness and mortality. ABPV, IAPV, and KBV infections can be lethal at times, especially in the presence of the parasitic *Varroa* mite. BQCV affects mainly developing queen larvae and pupae, causing infected pupae to turn dark and quickly die, with the wall of the queen cell becoming a dark color, a characteristic symptom of infection. The hymenopteran virus infections in honey bees have often been linked to worldwide colony losses, including the losses caused by the colony collapse disorder (CCD), a devastating malady that wiped out bees by the millions in the U.S. during the winter of 2006–2007.

The fecal-oral route features prominently in the transmission of SINV-1. Uninfected fire ants acquire SINV-1 infections when exposed to baits containing crude homogenates of SINV-1-infected worker ants and purified preparations of the virus. Virus transmission in this manner is easy and facilitates its use as a biopesticide (bait formulation) to control this pest ant. Fire ant colonies infected with SINV-1 can exhibit a chronic asymptomatic condition, or, under certain stressors, the colony exhibits significant mortality. Interestingly, SINV-1 prevalence in field colonies of fire ants is correlated strongly with increasing temperature; the virus prevalence is very high during warmer seasons and nearly undetectable during colder parts of the year.

TSV and Mud crab virus (MCV) are two dicistroviruses of crustaceans. MCV is associated with sleeping disease (SD) in farmed Portunidae crabs. TSV is responsible for one of the more devastating diseases of penaeid shrimp, Taura syndrome, which affects the aquaculture industry worldwide. TSV infects post larvae, juveniles and adult stages of shrimps; it has a broad range of tissue tropism and the infection can spread to different types of tissues, including the antennal gland, stomach, gill, lymphoid organ, sub-cuticle and connective tissues. TSV infection involves acute and chronic phases at the farm level. During the acute phase of the infection, infected shrimp display a variety of disease symptoms including anorexia, discoloration, lethargy and erratic swimming behavior. The mortality of infected hosts can be up to 95%. Shrimp that survive the acute stage pass through a transition phase and then become long-term (chronic) carriers of the virus.

The *Dicistroviridae* family consists of members whose hosts are agricultural and urban insect pests. SINV-1 was the first virus identified in the red imported fire ant, *Solenopsis invicta*, a pest whose sting is known to cause serious medical problems in people. SINV-1 infects all developmental stages and caste members of the fire ant, exhibiting a tissue tropism for gut tissue especially midgut. *S. invicta* queens infected with SINV-1 have lower body weights, reducing the probability of colony

founding. The potential use of SINV-1 as a biopesticide for pest control is currently under investigation. RhPV, ALPV, HiPV, and PSIV infect hemipteran pests that are important vectors of plant diseases. The viral infections primarily affect gut tissues of the hemipteran hosts. The host of TrV is a blood-sucking reduviid bug, which is an important vector of the protozoan parasite *Trypanosoma cruzi* responsible for Chagas disease in humans. TrV is the sole viral pathogen of triatomine bugs and replicates within the intestinal epithelial cells of the hosts, causing a delayed molting cycle and high mortality rate; its use as a biological control agent for vectors of Chagas disease has been proposed. HoCV-1 infects and causes increased mortality in the polyphagous glassy-winged sharpshooter, an important insect vector of the xylem-limited bacterial plant pathogen *Xylella fastidiosa*. CrPV. HoCV-1 grows rather efficiently in *Drosophila*, is highly pathogenic to the European olive fruit fly – a possible target pest for this virus.

Transmission of dicistroviruses involves both horizontal and vertical pathways. Transmission via ingestion and the alimentary canal feature prominently in dicistrovirus infection acquisition and transmission. Studies with hymenopteran dicistroviruses, ABPV, IAPV, KBV, and BQCV demonstrate that transmission in honey bees involves multiple pathways including food-borne, venereal, vector-borne, and vertical transmission. The detection of honey bee dicistroviruses in colony food stores, the digestive tract of infected bees, and feces suggests that horizontal transmission via the fecal-oral route is a prominent mechanism of dissemination. The detection of viruses in adult drones, semen, and the spermatheca of queens (the organ in which sperm is stored) implies transmission via the venereal route, where viruses are transmitted from infected males to females during mating. The route of horizontal transmission with the most consequence is by the parasitic mite *Varroa*. The varroa mite acquires and transmits the virus from infected bees to health bees. In addition to facilitating virus transmission, *Varroa* parasitism also suppresses honey bee immunity, thereby activating virus replication and increasing the susceptibility of infected hosts to further pathogenic infection. The detection of viruses in eggs as well as in the larval stages of bee hosts that are not normally associated with virus vector, suggests that viruses might be transmitted vertically from infected queens to her offspring.

Evidence of vertical transmission has also been identified in other dicistroviruses. ALPV RNA can be detected in the developing embryos inside infected females of the aphid host, *R. padi*, suggesting that ALPV can be vertically transmitted. RhPV can be transmitted not only vertically between aphid hosts but horizontally via the plant by using the plant as a passive reservoir. However, RhPV does not replicate in the plant. DCV is vertically transmitted and is associated with transovum transmission on the egg surface. A similar transovum transmission is also found with CrPV where the surface sterilization of eggs with dilute hypochlorite blocks the transmission of the virus to emerging nymphs.

Evidence of horizontal transmission is also documented for other dicistroviruses. The transmission of TSV is predominantly by cannibalism of infected or dead shrimp by healthy shrimp. The virus can also be spread from one farm to another farm by seagulls and aquatic insects. In the case of TrV and its host, *T. infestans*, the virus is transmitted through the fecal-oral pathway, where infected insects excrete the virus in their feces and healthy insects become infected by coprophagy. The leafhopper-infecting virus Homalodisca coagulata virus 1 (HoCV-1) spreads most readily in high population densities through contact among infected individuals, contact with virus-contaminated surfaces, and/or as an aerosol in leafhopper excreta. With DCV, the natural route of transmission in *Drosophila* is poorly characterized, as the majority of the virus infection assays in *Drosophila* utilize injection. However, when uninfected males are placed with uninfected females, the males become infected (and vice versa). In fact, even if uninfected female flies are placed on the same media that infected males have been allowed to feed on it for several hours, the females become infected, clearly indicating that the virus is transmitted horizontally among individuals.

Geographic and Strain Variation

Some dicistroviruses infect specific hosts with a wide geographic distribution or have been found to infect a number of species spread over a large geographic range. Several studies have looked at strain variations between geographic isolates of dicistroviruses using a variety of techniques. CrPV and DCV possess a range of biological and serological characteristics that show differentiation between geographical isolates. With CrPV, two major serogroups have been identified that separate Australian and New Zealand isolates from North American isolates. With DCV, isolates from different localities varied both in their pathogenicity and virus yield after being injected into virus-free flies. Additional genetic studies on CrPV and DCV have utilized ribonuclease T1 fingerprinting and subsequently polymerase chain reaction and restriction endonuclease analysis. Estimates of the maximum nucleotide divergence between isolates of CrPV and DCV were about 10%. In the case of CrPV, the North American isolates were quite distinct from the antipodean isolates, a finding that reflects the serological data.

More recently, a number of molecular studies with the honeybee dicistroviruses have been undertaken to determine the levels of genetic variation between isolates of these viruses. In most instances, slightly different regions of the virion protein coding regions (usual regions of VP3) have been used, which makes a direct comparison between studies quite difficult. Nevertheless, IAPV and ABPV isolates show levels of nucleotide identity between 90% and 100%, but isolates from the same geographic region are more closely related than isolates from more distant locations. One such study has revealed that viruses isolated from different central European regions were more similar to each other than to isolates from North America or from the UK. Similar patterns are also evident for BQCV and KBV with nucleotide identity within species at 90%–100%. To put these values into perspective, the region used for the KBV studies was 75% identical to the same region from ABPV.

For TSV, the situation is slightly different with nucleotide identities between isolates from North and Central America and Asia ranging from 95% to 100%. These lower levels of diversity may indicate that TSV has rapidly spread into many of the regions and hosts where it is now found, a hypothesis that is supported to some extent by the rapid emergence of the disease over the last two decades. There is also some evidence that suggests there are serological differences between isolates.

The RdRp region of the SINV-1 genome was sequenced from infected ant colonies collected from across the USA, northern Argentina, and northern Taiwan. Nucleotide sequences were calculated to exhibit an overall identity of >90% between geographically-separated samples. A total of 171 nucleotide variable sites (representing 22.4% of the region amplified) were mapped across the SINV-1 RdRp alignment and no insertions or deletions were detected. Phylogenetic analysis at the nucleotide level revealed the clustering of Argentinean sequences, distinct from the USA sequences. SINV-1 RdRp sequences derived from populations of *S. invicta* from northern Taiwan resided within the multiple USA groupings.

Relationships Within the Family

Phylogenetic relationships with the *Dicistroviridae* family are depicted in Fig. 3. The three genera, *Aparavirus*, *Cripavirus* and *Triatovirus*, form distinct clades. Triatoviruses are distinct from aparaviruses and cripaviruses by the presence of prominent projections on the virion surface and a DDF motif in the homologous location in VP3 and the absence of icosahedrally ordered VP4. Aparaviruses and cripaviruses are different from each other in their distinctive features exhibited in the IRES. The typical IGR-IRES of cripaviruses has a conserved bulge sequence (UGAUCU and UGC), while those of aparaviruses have a different bulge sequence (UGGUUACCCAU and UAAGGCCUU) and an additional stem loop in the 3' region of the IGR-IRES. Phylogenetic analysis of deduced amino-acid sequences of the three major coat proteins (ORF 2) shows three distinct clades (Fig. 3), supporting the classification of species into three genera in the *Dicistroviridae* family.

Fig. 3 Phylogenetic tree constructed from the amino acid identity of the structural proteins encoded by ORF2 shows the relationships among members of the family *Dicistroviridae*. Numbers on the branches indicate percentage of bootstrap support out of 1000 replications. The scale indicates amino acid distance. The tree was generated using neighbor-joining algorithm implemented in MEGA7.

Similarity With Other Taxa

Members in the family *Dicistroviridae* have similarities with viruses in the families *Iflaviridae*, *Picornaviridae*, *Marnaviridae*, and *Secoviridae*. The genomes of viruses of these taxa are positive sense ssRNAs with a VPg and a poly (A) tail, and are translated into autoproteolytically processed polypeptide(s). Nonstructural proteins contain sequence motifs for helicase (Hel), 3C-like cysteine proteinase (Pro) and RNA-dependent RNA polymerase (RdRp) with the characteristic gene order: (Hel)-(Pro)-(RdRp). Virions contain capsid proteins organized in a module containing three related jelly-roll domains that form non-enveloped, isometric particles of pseudo $T = 3$ symmetry and 30 nm diameter.

Acknowledgments

We would like to thank Dr. Peter D. Christian for all his help and support.

Glossary

Antagonist An agent that binds a target consequently blocking or dampening a biological process.

Cytopathic effect Structural changes of infected cells resulting from a viral infection.

Metagenome Summary of all genomes and genes obtained from an environmental sample. The data are generated through non-targeted shotgun sequencing of nucleic acids extracted from the sample.

Open reading frame Continuous stretch of codons that begins with a start codon and ends at a stop codon which has the ability to be translated into a protein.

Phylogenetic clade A group of organisms derived from a common ancestor species.

Positive-sense Also known as 'plus-stand' which refers to the translation sense of the viral RNA (5' to 3') that may be directly translated into the desired viral proteins.

Protease An enzyme that cuts or cleaves proteins.

Prototype virus The first representative virus of a species or genus.

Ribonucleoprotein complex A nucleoprotein that contains RNA.

RNA interference A biological mechanism of inhibiting gene expression or translation. Interfering RNA molecules bind certain mRNA molecules, leading to their neutralization.

Classification (Compact)

Entomobirnaviruses are small RNA viruses that infect exclusively insects and they are the only ones in the *Birnaviridae* family that do. When discovered in 1958 during a series of experiments with Sigma virus (genus *Sigmavirus*, family *Rhabdoviridae*), the prototype entomobirnavirus *Drosophila* X virus was identified as a contaminant in laboratory-reared fruit flies of the species *Drosophila melanogaster* (Table 1). The virus has also been detected in various *Drosophila melanogaster* cell lines. However, *Drosophila* X virus has not yet been detected in wild populations and thus its origin is still unclear. It was speculated that it could have pre-existed in *Drosophila* broods in a non-pathogenic form or that it might have originated as a contaminant in fetal bovine serum used in cell culture. Over 50 years later, published in 2012, the first tentative entomobirnavirus was identified in free-living insects.

Table 1 Classified and unclassified entomobirnaviruses, their host, country, and year of initial detection. Accession numbers provided refer to the NCBI GenBank database (<https://www.ncbi.nlm.nih.gov/genbank/>).

Fig. 1 Phylogenetic relationship of entomobirnaviruses. Phylogenetic analysis of entomobirnaviruses and prototype members of the birnavirus genera *Avibirnavirus*, *Blosovirus*, and *Aquabirnavirus*. Pictograms illustrate the source of the respective virus: laboratory contamination, mosquito, fruit fly.

Culex Y virus was isolated from hibernating *Culex pipiens* complex mosquitoes collected in a cave in Bad Segeberg, Germany. Today, natural infections with entomobirnaviruses have been detected in *Drosophila immigrans* and in various Culicidae sp. mosquitoes of France, China, Germany, and the United Kingdom.

The genus *Entomobirnavirus* belongs to the family *Birnaviridae* and is currently one of four established genera (Fig. 1). Entomobirnaviruses form a monophyletic clade within the family *Birnaviridae* and are distantly related to the other three birnavirus genera that comprise vertebrate infecting viruses. Apart from the species *Drosophila X virus*, which is represented by the prototype entomobirnavirus *Drosophila X virus*, a second species, *mosquito X virus*, has formally been established in the genus. In addition, there are six unclassified but suggested entomobirnaviruses that have not yet been officially assigned to species in the genus (Table 1). *Drosophila X virus* is a widely used model pathogen for the study of different RNAi mechanisms in insect cells. As an insect virus, *Drosophila X virus* can be propagated in cell culture under standard laboratory conditions.

Together with Eridge virus, which has been detected in *Drosophila immigrans* during a metagenomic study, *Drosophila X virus* forms a sister clade to the other five mosquito-associated entomobirnaviruses: Espirito Santo virus, *Culex* Y virus, *mosquito X virus*, culicine-associated Z virus, and Port Bolivar virus (Fig. 1). However, the host of Espirito Santo virus remains unknown as it has been detected in an *Aedes albopictus* cell line inoculated with serum from a Dengue virus (genus *Flavivirus*, family *Flaviviridae*) infected patient. In addition, Thirlmere virus has been isolated from a water sample in cells derived from *Drosophila melanogaster* (Table 1). The virus failed to replicate in other insect, plant and various vertebrate cells. A relationship between Thirlmere virus and *Drosophila X virus* has been determined based on antigenic, biochemical, and physical properties. The genome of Thirlmere virus has not yet been sequenced.

Virion Structure

Like other members of the family *Birnaviridae*, entomobirnavirus virions are non-enveloped with a capsid made by the viral protein 2 (VP2) and a diameter of about 60–70 nm (Fig. 2). *Drosophila X virus* particles have a density of 1.345 g/ml. The virions contain ribonucleoprotein complexes formed by the genome and multiple copies of the capsid protein.

Genome

Like all birnaviruses, entomobirnaviruses possess a bisegmented, linear, double-stranded RNA genome encoding several viral proteins (VP). Segment A of *Drosophila X virus* is about 3.4 kbp in length and encodes a 114 kDa polypeptide precursor preVP2-VP4-VP3. The VP4 (24 kDa) is a viral serine-alanine protease that releases preVP2 (55 kDa) and VP3 (35 kDa) by cleavage of its own N- and C-termini in the polypeptide (Fig. 3). In *Drosophila X virus* the cleavage sites are located at Ser₅₀₀/Ala₅₀₁ (preVP2 and VP4) and Ser₇₂₃/Ala₇₂₄ (VP4 and VP3), respectively (Fig. 3). The mature VP2 (47 kDa), which represents the viral capsid protein and type-specific antigen, is generated by subsequent serial cleavages of small peptides at the C-terminus of preVP2 most likely via cellular proteases. In mature virus particles VP2 dominates, however progenitor proteins, including preVP2, can also be found. Multiple copies of the nucleoprotein VP3 are associated with the two genome strands forming ribonucleoprotein complexes inside the virion. It has also been shown that VP3 has an RNAi antagonistic function to suppress antiviral RNAi. An additional protein of unknown function (VP5, 27 kDa) is encoded by a small 714 nucleotide, internal open reading frame. In contrast to *Drosophila X virus*, Eridge virus, Espirito Santo virus, and Port Bolivar virus the initiation codon AUG of this open reading frame is mutated to GUG in *Culex* Y virus, *mosquito X virus*, and culicine-associated Z virus (Fig. 3). This open reading frame is likely to be expressed

Fig. 2 Infected cells and purified virus particles of Culex Y virus. *Aedes albopictus* cells infected with Culex Y virus 24 h post infection. Cells show cell aggregation as a consequence of the infection with the virus (A). Electron microscopy of purified Culex Y virus particles. Particles were negative stained using uranyl acetate and suggest icosahedral symmetry. Scale bar represents 100 nm (B).

Fig. 3 Schematic representation of entomobirnavirus genome organization. Numbers refer to nucleotide and amino acid sequence position in the genome and proteins of Drosophila X virus. Protease cleavage sites are shown in bold. VPg = genome-linked RNA-dependent RNA polymerase (VP1).

by a -1 ribosomal frame shift that gets facilitated by a particularly shift-prone (“slippery”) sequence (5′-...UUUUUUA...) located 22 nucleotides downstream of the VP5 initiation codon and is conserved among entomobirnaviruses.

Segment B of Drosophila X virus is about 3.2 kbp in length. It encodes the VP1 protein which represents the viral RNA-dependent RNA polymerase. This protein is covalently linked to the 5′-end of the positive-sense genome strand of both segments (VPg), though free forms can be found inside the virion (Fig. 3). Like all RNA viruses, entomobirnaviruses carry highly conserved motifs in their polymerases that are believed to correspond to RNA polymerase functions. However, entomobirnaviruses are lacking the highly conserved Gly-Asp-Asp (GDD) motif that is postulated to form the catalytic site of RNA virus polymerases. Instead, the entomobirnavirus Drosophila X virus RdRp contains three downstream Asp-Asp (DD) residues. They may function as homologs but are located in a more spatially distinct region than the conserved GDD motif in RNA virus polymerases. Due to this the polymerase of entomobirnaviruses may form a distinct subgroup of RNA virus polymerases.

Life Cycle

Knowledge of the replication cycle of entomobirnaviruses is scarce. Transcription and replication are facilitated by the viral RNA-dependent RNA polymerase (VP1). The VP1 protein of Drosophila X virus contains a consensus GTP-binding site and likely has a self-guanlylation activity. Genome replication takes place in the cytoplasm. Translation is performed by the cellular machinery using capped mRNAs that are lacking 3′-poly (A) sequences. Mature virus particles can be found scattered or arranged as crystalline arrays in the cytoplasm.

Epidemiology

Due to their insect-specificity, entomobirnaviruses do not have epidemiological significance. However, entomobirnaviruses have been shown to be present in free-living insects in China, the United States, and different countries in Europe.

Clinical Features

Infections with the entomobirnavirus *Drosophila* X virus have been determined to cause oxygen starvation in *Drosophila melanogaster*. The symptoms occur three to four days before death in dose-dependent *in vivo* experiments. However, these flies and *Drosophila*-derived cell lines can also be persistently infected.

Pathogenesis

Knowledge on the pathogenesis of entomobirnaviruses is scarce. *Drosophila melanogaster* flies infected with *Drosophila* X virus showed a wide distribution of virus particles in the brain, digestive tract, muscles, Malpighian tubules, ovaries, testis, and thorax. Flies that have been examined directly after the onset of anoxia showed that gut and trachea cells, as well as the muscle sheath of different organs were mainly affected. It is speculated that an early invasion of trachea cells by the virus leads to the sensitivity of flies to anoxia.

Experimental infections of various vertebrate and plant cell lines showed no replication of these viruses in non-insect cells. *Culex* Y virus, Espirito Santo virus, and Port Bolivar virus, cause a cytopathic effect (CPE) in different cell lines derived from *Aedes albopictus* (Fig. 2). The CPE is lethal to the cells and they die shortly after being infected with the virus. In contrast, *Drosophila* X virus and Thirlmere virus are not able to infect cells of *Aedes albopictus*.

Hytrosaviruses (*Hytrosaviridae*)

Henry M Kariithi, Kenya Agricultural and Livestock Research Organization, Nairobi, Kenya

Irene K Meki, French National Center for Scientific Research, Montpellier, France

© 2021 Elsevier Ltd. All rights reserved.

Nomenclature

Hytrosa Is derived from two Greek words: “*hypertrophia*” (“excess nourishment”) and “*sialoadenitis*” (“salivary gland inflammation”)

Hytrosaviridae Is a family of entomopathogenic dsDNA viruses that infect dipteran insects

Glossary

Aposymbiotic Is an organism that is functionally devoid of its natural symbiont (mutualist, commensalist, or parasitic).

Corpora allata/cardiac Are a complex of endocrine glands that secrete and store juvenile hormones, which are involved in the regulation of metamorphosis and tissue development in insects.

Horizontal transmission Is the direct (e.g., air-borne, food-borne or venereal) or indirect (e.g., intermediate host vector) transmission of an organism among related or unrelated individuals of the same generation of an ecosystem.

Hyperplasia Is enlargement of an organ or tissue caused by an increased proliferation of cells, which become multi-layered and are capable of replication.

Hypertrophy Is enlargement of an organ or tissue from increased size of cells, which are incapable of dividing.

Hytrosa Is derived from “*hypertrophia sialoadenitis*”, the Greek words meaning “excess nourishment” and “salivary gland inflammation”, respectively.

Peritrophic matrix Is a semipermeable membranous layer that lines the insect gut and is composed of proteins, glycoproteins and chitin microfibrils.

Vertical transmission Is the transovum (egg surface) or transovarian (within the egg) transmission of an organism among individuals of the same generation (e.g., from a mother to its offspring).

Vitellogenesis Is the process of egg yolk formation through deposition of nutrients into oocytes or female germ cells involved in reproduction of lecithotrophic (non-feeding larval development) organisms.

Introduction

Hytrosaviruses (also known as salivary gland hypertrophy viruses or SGHVs; *Hytrosaviridae* family) are rod-shaped, enveloped viruses with large, circular double-stranded DNA (dsDNA) genomes of 120–190 kbp in length. These viruses infect the hematophagous tsetse fly (Diptera: Glossinidae), the filth-feeding common housefly, *Musca domestica* (Diptera: Muscidae) and the phytophagous syrphid fly, *Merodon equestris* (Diptera: Syrphidae). The distinguishing diagnostic feature of SGHV infections is the induction of salivary gland hypertrophy (SGH) syndrome in the salivary glands (SGs) of their adult insect hosts. Observations of a morphologically (rod-shaped viral particles) and symptomologically (occurrence of SGH symptoms) similar virus in the male accessory gland filaments of the solitary braconid wasp, *Diachasmimorpha longicaudata* Ashmead, (Hymenoptera: Braconidae) suggests existence of SGHVs in other insect hosts. The intrinsic properties of SGHVs (i.e., chronic covert infection of adult stages of their hosts), combined with the need to dissect SGs for diagnosis probably hinder the discovery of more members of the *Hytrosaviridae* family.

The SGH symptoms were first reported in the tsetse species *Glossina pallidipes* in the early 1930s in Zululand, South Africa, during a survey of the prevalence of African trypanosomes, the causative agents of Africa's ancient scourge, African trypanosomiasis (sleeping sickness and nagana in humans and animals, respectively) (see [Table 1](#)).

Three decades later (1970s and 1980s), SGH symptoms were noted to occur twice as often in males than in females, to favor development of *Trypanosoma* parasites, and to cause reproductive dysfunctions in the infected flies. The second description of SGH was in 1970s in southern France in 31% and 54% of sampled populations of *M. equestris* var. *nobilis* and *M. equestris* var. *transverlis*, respectively. The third report of SGH symptoms was in the 1990s in adult populations of *M. domestica* at a dairy farm in Florida, USA, during a survey of parasitic nematode infections.

Of particular interest is the negative impacts of SGHV infections in tsetse mass production factories. These factories are required for production of sexually sterile males that are used for tsetse vector control via the environmentally friendly sterile insect technique (SIT), an insects' birth control with a solid track record. For instance, in the 1980s, a *G. pallidipes* colony maintained at the now defunct Kenya Trypanosomiasis Research Institute in Kenya collapsed unexpectedly a few years after its establishment due to poor productivity. Subsequent SGH outbreaks caused collapse of two more *G. pallidipes* colonies at a tsetse production facility in Seibersdorf, Austria (1987 and 2001), and another colony at Kaliti in Ethiopia (in 2012). The poor productivity and eventual collapse of the Seibersdorf colonies jeopardized the implementation of an ambitious SIT-mediated control of *G. pallidipes* from a

Table 1 Chronological history of the discovery and characterization of SGHVs

Year	Milestones in SGHV research
1930–1940	First observation of salivary gland hypertrophy (SGH) syndrome in <i>Glossina pallidipes</i> in Zululand, South Africa. SGH symptoms noted to preferential occur more in males than females
1970–1979	- SGHV reported in other tsetse species (<i>G. morsitans</i> and <i>G. fuscipes</i>). - SGHV reported in two varieties of the narcissus bulb fly (<i>Merodon equestris</i> vr. <i>nobilis</i> and <i>M. equestris</i> vr. <i>transversalis</i>) in southern France.
1980–1989	- SGH reported to be a common diagnostic feature in wild populations of <i>G. pallidipes</i>. - Collapse of a <i>G. pallidipes</i> colony in Kenya attributed to SGHV infections. - Demonstration of <i>per os</i> transmission of infectious GpSGHV particles in tsetse flies. - SGHV shown to reduce insemination rates, fecundity and lifespan of colonized <i>G. pallidipes</i>. - Reports of SGH symptoms in tsetse flies from Zimbabwe and Côte d'Ivoire. - SGHV linked to poor productivity of two <i>G. pallidipes</i> colonies maintained at the Insect Pest Control Laboratory (IPCL) in Seibersdorf, Austria.
1990–1999	- SGHV demonstrated to be transmitted from artificially infected mothers to their offspring. - First description of SGHV cytopathology in tsetse salivary glands. - SGHV infections reported in <i>G. morsitans Swyenatoni</i> and <i>G. brevipalpis</i>. - SGHV reported for the first time in the housefly, <i>Musca domestica</i> L in Florida, USA. - SGHV shown to infect milk glands, mid-gut and male accessory glands of <i>G. pallidipes</i>.
2000–2009	- Collapse of an Ethiopian-derived <i>G. pallidipes</i> colony at IPCL, Seibersdorf, Austria. - SGHV shown to infect male accessory glands of <i>G. m. morsitans</i> Westwood. - Full sequencing of genomes of GpSGHV and MdSGHV. - GpSGHV and MdSGHV proposed and established in a new virus family, <i>Hytrosaviridae</i>. - Transcription analysis of MdSGHV.
2010–2018	- Description of the full proteome, ultra-structural features and morphogenesis of GpSGHV. - Demonstration of global distribution of MdSGHV in <i>M. domestica</i> populations. - SGHV-like virus described in accessory gland filaments of the solitary braconid wasp <i>Diachasmimorpha longicuada</i>. - Antiviral drugs (valacyclovir/acyclovir) demonstrated to interrupt GpSGHV replication in <i>G. pallidipes</i>. - Demonstration that microbiota influence vertical transmission of GpSGHV in <i>G. pallidipes</i>. - Successful management of GpSGHV infections and complete eradication of overt SGH symptoms in <i>G. pallidipes</i> colonies using combination of antiviral drugs and modified feeding regimes. - GpSGHV shown to modulate different molecular pathways in <i>G. pallidipes</i> and <i>G. m. morsitans</i>. - Full sequencing of genome a GpSGHV strain from Ethiopian tsetse flies. - The first evidence that microRNAs (miRNA) and RNA interference (RNAi) are involved in GpSGHV infections in <i>G. pallidipes</i>.

25,000 square kilometers of under-utilized fertile land in the Southern Rift Valley of Ethiopia. The Ethiopian SIT project was to be a model demonstrating that tsetse flies can be eradicated from the mainland Africa, after the hailed successful eradication of *G. austeni* populations on Zanzibar Island. These turns of events precipitated into concerted research efforts to characterize the tsetse virus and develop integrated mitigation strategies to salvage tsetse mass production. The research also included the housefly-infecting virus, which was deemed as a potential risk in the magmeal production industry and as a biocontrol agent due to its ability to suppress ovarian development in the insect.

To date, genomes of two strains of SGHVs from different tsetse fly populations, and one strain from the housefly have been fully sequenced.

Taxonomy and Classification

When first discovered, the tsetse SGHVs were described as “virus-like particles” due to their morphological resemblance to viruses that had already been described in other organisms such as the *Drosophila*, mosquito, and nematodes. The SGHVs were erroneously presumed to be arboviruses (based on their morphological similarities to other viruses that replicate in the SGs and are transmitted by hematophagous insects such as mosquitoes, ticks, sand flies and gnats), or nudiviruses (based on their sizes and enveloped rod-shaped morphology). However, full genome sequencing data of SGHVs in 2008 did not support the placement of these viruses within any of the established families of invertebrate viruses. The tsetse fly and housefly SGHVs showed limited but significant gene homologies, and were subsequently classified into separate genera within a new *Hytrosaviridae* family. *Glossina pallidipes* salivary gland hypertrophy virus (GpSGHV) is classified in the type species *Glossina hytrosavirus* of the genus *Glossinavirus* and *Musca domestica* salivary gland hypertrophy virus (MdSGHV) is classified in the species *Musca hytrosavirus* of the genus *Muscavirus*. The name of the virus family (Hytrosa) was derived from the Greek words *Hypertrophia* and *sialoadenitis*, meaning “excess nourishment” and “salivary gland inflammation”, respectively. Compared to GpSGHV, MdSGHV is more structurally and symptomologically similar to the virus that induces SGH symptoms in *M. equestris* (MeSGHV).

Fig. 1 Maximum likelihood (ML) phylogenetic trees of conserved hytrosaviruses (SGHVs) genes. Based on DNA polymerase, SGHV relate more closely with linear dsDNA viruses (e.g., *Herpesviridae*, *Iridoviridae* and *Phycodnaviridae*) than circular dsDNA viruses (A). Panels B and C show ML trees of concatenated sequences of *per os* infectivity factors (P74 or PIF-0, PIF-1, PIF-2 and PIF-3) and ODV-E66, respectively. SGHV PIFs branched more distantly from nudiviruses than from baculoviruses. GenBank accession numbers of the viruses are indicated in tree branches (square brackets). *Virus abbreviations*: ASFV, African swine fever virus; GpSGHV-Uga/Eth, *Glossina pallidipes* SGHV Uganda/Ethiopia strain; MdSGHV, *Musca domestica* SGHV; HHV-6B, Human betaherpesvirus 6B; PCMV, Porcine cytomegalovirus; BoHV-1, Bovine herpesvirus 1; RFHV, Retroperitoneal fibromatosis-associated herpesvirus; MfRV, *Macaca fuscata* rhadinovirus; ApMV, *Acanthamoeba polyphaga* mimivirus; PbCV-1, *Paramecium bursaria* Chlorella virus 1; EsV-1, *Ectocarpus siliculosus* virus 1; SfAV-1a, *Spodoptera* ascovirus 1a; LDV-1, Lymphocystis disease virus 1; IIV-6, Invertebrate iridescent virus 6; AtIV, *Aedes taeniorhynchus* iridescent virus; AmEPV, *Amsacta moorei* entomopoxvirus L; ChEP, *Choristoneura biennis* entomopoxvirus L; VACV, *Vaccinia* virus; McV, *Molluscum contagiosum* virus; WSSV, Shrimp white spot syndrome virus; NeleNPV, *Neodiprion lecontei* nucleopolyhedrovirus; NeabNPV, *Neodiprion abietis* nucleopolyhedrovirus; HearNPV, *Helicoverpa armigera* nucleopolyhedrovirus; CpGV, *Cydia pomonella* granulovirus; PxGV, *Plutella xylostella* granulovirus; AcMNPV, *Autographa californica* multiple nucleopolyhedrovirus; LdMNPV, *Lymantria dispar* multiple nucleopolyhedrovirus; SeMNPV, *Spodoptera exigua* multiple nucleopolyhedrovirus; OpMNPV, *Orygia pseudotsugata* multiple nucleopolyhedrovirus; OrNV, *Oryctes rhinoceros* nudivirus; HznV-2, *Helicoverpa zea* nudivirus 2; HznV-1, *Heliothis zea* nudivirus 1; GbNV, *Gryllus bimaculatus* nudivirus; PmNV, *Penaeus monodon* nudivirus; HgNV, *Homarus gammarus* nudivirus.

Similarities With Other Virus Taxa

GpSGHV and MdSGHV are structurally similar to members of other arthropod-infecting virus families such as *Baculoviridae*, *Nudiviridae*, and *Nimaviridae*. The SGHVs share 12 of the 38 core genes that have been described in baculoviruses, nudiviruses, nimaviruses, and some bracoviruses. Among the structural and genomic features shared by SGHVs and other large dsDNA viruses include possession of enveloped, rod-shaped virions, circular dsDNA genomes and their replication in the nucleus of infected insect cells. However, the SGHVs functionally differ from viruses such as the baculoviruses in the lack of occlusion bodies and lower lethality (i.e., SGHVs rarely kill their insect host).

Based on the DNA polymerase II (B-family; polB) gene, which is present and conserved in all large dsDNA viruses, SGHVs relate more closely with invertebrate large linear dsDNA viruses compared to circular dsDNA viruses. The linear dsDNA viruses that cluster together with SGHVs include members of families *Herpesviridae* (120–240 kb), *Iridoviridae* (140–303 kb), *Poxviridae* (130–375 kb), *Phycodnaviridae* (100–560 kb), and *Mimiviridae* (1200 kb) (Fig. 1(A)). At the amino acid level, the polB of GpSGHV and MdSGHV are 31% identical, and their best matches are to the alcelaphine herpesvirus polB (24.9% and 22.6% identities, respectively).

The most significant similarity between the SGHVs and other large invertebrate dsDNA viruses is the possession of genes encoding four of the core and highly conserved *per os* infectivity factor proteins (PIFs 0 or P74, 1, 2, and 3) (Fig. 1(B)). The PIFs are essential for entry of baculoviruses and nudiviruses in their host's midgut cells. At the amino acid level, the GpSGHV and MdSGHV PIF homologs are closely related (31%–39% identical) and appear to have evolutionarily diverged more distantly from nudiviruses than from baculoviruses. The genomes of SGHVs also encode homologs to a late expression protein, and a major structural component of occlusion-derived virus (ODV) envelopes of lepidopteran baculoviruses (ODV-E66 protein). ODV-E66 is a chondroitinase that plays roles during baculovirus infections in the midguts of lepidopteran larvae. The ODV-E66 of SGHVs cluster together with their homologs in baculoviruses (Fig. 1(C)), but its role during the SGHV infection has not been established.

In addition to polB and PIFs, the two SGHVs encode homologs to four of the six subunits of the DNA-dependent RNA polymerase (DdRp) complex reported in baculoviruses and nudiviruses. DNA viruses use the DdRp to transcribe their mRNAs. The DdRp complex subunits present in SGHVs include the late expression factors 4, 5, 8, and 9 (LEF-4, LEF-5, LEF-8, and LEF-9). The multifunctional LEF-4 is an mRNA capping enzyme, LEF-5 is a transcription initiation factor, and LEF-8 plays critical roles in the activation of the late gene promoter, while LEF-9 forms a part of the catalytic center of the DdRp complex. It is notable that whereas LEF-9 is encoded by a single open reading frame (ORF) in MdSGHV, baculoviruses and nudiviruses, GpSGHV has two adjacent ORFs coding for the N- and C-terminals of this enzyme. Both GpSGHV and MdSGHV lack homologs to the remaining two of the six DdRp subunits, i.e., P47 and very late expression factor 1 (VLF-1) proteins, which play roles in systemic viral infections, and capsid assembly/viral DNA packaging, respectively.

Taken together, the presence of the above-mentioned gene homologs in the SGHVs suggests their common ancestry and similar modes/mechanisms of entry into the host cells and gene expression.

Virion Structure

The MdSGHV and GpSGHV virions are 50–65 nm in diameter, non-occluded, non-icosahedral rod-shaped particles measuring 500–1000 nm in length, and contain a bilayer lipid envelope. The SGHV particles have a density of 1.153 g cm^{-3} on a 10%–60% Nycodenz gradient. There are however distinct morphological differences between the SGHV virions. The rigid and rod-shaped GpSGHV virions are longer (50–65 nm $\times$ 1000 nm) compared to those of MdSGHV (65 nm $\times$ 550 nm). The enveloped virions of the unclassified MeSGHV measure 50–60 nm in diameter and 500–600 nm in length. The GpSGHV virions are asymmetrical with a rounded and a conical end, and consist of a thin, central, electron-dense helical nucleocapsid core (40 nm in diameter). The nucleocapsid core is surrounded by a 10 nm-thick proteinaceous tegument matrix, which is encapsulated by an outer lipid bilayer envelope. The outer surface of the virion is studded with left-handed helical polymeric spikes (13 nm long with 15 nm periodicity) composed of viral and host-derived protein dimers (23 spikes $\times$ 24 helical turns = 1104 envelop dimers). GpSGHV particles are more fragile (the viral envelopes are readily depleted by treatment with common buffers), which partially accounts for their low infectivity compared to the MdSGHV particles. The MdSGHV virions have regularly spaced braided, bead-like surface topology and are rounded on both ends.

Genome Organization

Detection of relaxed and supercoiled bands after gel electrophoresis of purified viral DNA, and the absence of end-labeling of undigested DNA suggested that SGHV genomes were circular dsDNA molecules. Currently, two strains of GpSGHV isolated from Ugandan (GpSGHV-Uga; GenBank Acc. no. EF568108) and Ethiopian *G. pallidipes* (GpSGHV-Eth; GenBank Acc. no. KU050077.1) have been fully sequenced. The organization and the main features of the genome of GpSGHV-Eth compared to that of GpSGHV-Uga are schematically represented in Fig. 2. The conserved regions of GpSGHV-Uga and GpSGHV-Eth genomes are 98.1% similar at the nucleotide level. However, compared to the GpSGHV-Uga, the GpSGHV-Eth genome has insertions and deletions in 17 and 20 ORFs, respectively, while 11 ORFs are deleted and 24 ORFs are novel. Only one MdSGHV strain has so far been fully sequenced (MdSGHV GenBank Acc. no. NC_010671.1), but other uncharacterized isolates of the virus have been detected in housefly populations sampled from various geographical locations. The MdSGHV genome presumably has similar genome organization as that of GpSGHV.

The GpSGHV-Uga, GpSGHV-Eth and MdSGHV differ in their genome sizes (190,032 bp, 190,291 bp and 124,279 bp, respectively), and G + C contents (28.0%, 27.9% and 43.5%, respectively). Approximately 2.8% and 1.7% of the GpSGHV and MdSGHV genomes, respectively, harbor tandem direct repeat sequences (*drs*). The numbers and sizes of the *drs* differ among the SGHV strains: 14 *drs* (52–147 bp) in GpSGHV-Eth, 15 *drs* (52–246 bp) in GpSGHV-Uga, and 18 *drs* (30–380 bp) in MdSGHV. The *drs* are clustered in some genomic regions, but they are less clustered in MdSGHV than in GpSGHV. Three GpSGHV-Eth *drs* (dr9, 11, and 13) and seven MdSGHV *drs* (dr5, 6, 7, 10, 16, 17, and 18) are localized within coding regions of specific ORFs. All the GpSGHV-Uga *drs* are localized in noncoding regions. In baculoviruses, similar repeat regions are usually located between genes, and are hypothesized to influence viral replication (as transcription enhancers and/or origins of DNA replication), evolution, and pathobiology. The SGHVs lack the palindromic homologous repeat (*hrs*) regions found in other invertebrate circular dsDNA viruses such as baculoviruses, nudiviruses and nimaviruses.

Most of the ORFs in the genomes of GpSGHV harbor the TATA-like box promoter elements (89.7%), poly(A) signals (83.9%), and late transcriptional initiation motifs (T/G/A)TAAG (35.5%). The transcriptional elements in the MdSGHV genome are largely unknown, but most of its ORFs are enriched with the TAAG motifs, poly(A) signals and TATA-like box promoter elements. Notably, 13 GpSGHV-Eth genes are non-canonical, five of which are homologs to known regulatory genes, including the *MAL7P1.132* gene, *lef-9*, thymidylate synthase (*ts*), cluster of differentiation antigen protein-48 (*cd-48*) and metalloendopeptidase (*mp-nase*).

Modes of Infection and Gene Expression

The mechanism(s) of SGHVs life cycle within their insect hosts is unclear. Proteomic and transcriptomic studies have however provided evidence for the expression of *pif* genes, but it is unclear whether PIFs are involved in the virus initial attachment and

Fig. 2 Circular representation of the GpSGHV-Eth genome and its comparison (percentage identity) to the GpSGHV-Uga genome. The open reading frames (ORFs) are presented starting with the ATG initiating codon of the *p74* gene (coded by SGHV-Eth001). The outermost two concentric rings and the arrows represent the positions and orientations of the transcription potential of each ORF. BLASTn comparison (98.1% identity at the nucleotide level) between the two SGHV genomes is indicated by the third ring (from outside). The black peaks represent the deviation from the average % G + C content of the entire genome. ORFs are color-coded based on their homologies between the two genomes as shown in the figure key. The names of the annotated ORFs are indicated. Unlabeled ORFs (light gray color) represent hypothetical/uncharacterized ORFs. The figure is drawn to scale. *Gene abbreviations:* *odv-e66*, occlusion-derived virus envelope protein 66; *paxp-1*, paired box protein Pax-1; *lef*, late expression factor; *ADPRase*, ADP-ribose pyrophosphatase; *pif*, per os infectivity factor; *RpoD*, RNA polymerase sigma (σ) factor; *cd-48*, Cell division cycle protein 48; *chmU*, chlacomycin gene U; *cg-30*, Zinc finger protein CG30; *pe38*, Major immediate early protein 38; *gadd-34*, growth arrest and DNA damage protein 34; *trap*, trp RNA-binding attenuation protein; *bcr-abl*, an oncogene arising from the fusion of the breakpoint cluster (*bcr*) gene with chromosomal Abelson murine leukemia (*c-abl*) proto-oncogene; *ABC transporter*, ATP-binding cassette transporter.

infection of the host's midgut epithelial cells. Available data suggest low frequency of *per os* infection, most likely due to the peritrophic matrix (PM) barrier that may reduce the penetration of viral particles into the hemocoels. Following initial oral infection, SGHVs exploit the host's tracheal system as a conduit to breach the basal laminal barrier in the midgut to access the SGs, the primary tissue of viral replication. Viral capsids are released into the cell cytoplasm via fusion of viral and host's vesicle membranes, and then trafficked (via the host's microtubule motor complexes) to the cell nucleus for viral gene transcription, viral DNA genome replication, packaging and assembly of progeny nucleocapsids in the virogenic stroma.

Based on the complexity and significant homologies of SGHV-expressed proteins to well-annotated proteins in other viruses, the current school of thought is that the viral replication involves sequential expression of the immediate early (transcription factors), early (DNA replication genes), and late (viral replication proteins) genes. However, a lack of a suitable cell culture to support SGHV replication has so far hindered the elucidation of the precise transcriptional timings of the SGHV genes. Transmission electron microscopy (TEM) has provided evidence that the SGHV nucleocapsids exit the nucleus of infected SG cells via the nuclear pore complex, and subsequently acquire their glycoprotein-containing envelopes in the cell cytoplasm, presumably via the ER-Golgi system. After maturation, the enveloped viral particles egress by migrating to and budding out of the cell membranes bordering the SG lumens (for MdSGHV) or lysis of the luminal cell membranes (for GpSGHV).

Major Structural Proteins

Proteomic studies have revealed that the SGHV structural complex comprise of a blend of virally-encoded and host-derived proteins, with the nucleocapsid and envelope sections of the GpSGHV and MdSGHV virions composed of at least 45 and 29 structural proteins, respectively. Of the GpSGHV structural proteins, 10, 15, and 20 proteins are localized in the envelope, nucleocapsid, and tegument matrix, respectively. The structural proteins in GpSGHV and MdSGHV are almost identical, most of

which are homologs to structural proteins described in several insect viruses. The major structural proteins of GpSGHV, their homologs in other invertebrate dsDNA viruses and their functional annotations are summarized in **Table 2**.

As shown in **Table 2**, the most notable GpSGHV nucleocapsid structural proteins include homologs involved in viral DNA assembly and encapsidation, chromosomal structural positioning, and protein turnover during late viral infection. Amongst the homologous structural tegument proteins include those involved in the disruption of the plasma membrane to initiate infection, nucleocapsid egress from virogenic stroma, and hijacking of the host cell ubiquitin machinery. Notable envelope structural proteins include homologs involved in oral infection, viral replication and late gene expression, correct virus assembly, and morphogenesis of infectious virions. Additionally, there are proteins that could not be associated with the structural (nucleocapsid, tegument, envelope) components of GpSGHV, and were assigned as “infected cell-specific viral proteins” (ICSVs). Notable ICSVs include homologs to proteins essential for viral DNA replication, late and very late viral transcription, nucleocapsid envelopment, and terminal host liquefaction (**Table 2**). Other than the virally-encoded proteins, a mature GpSGHV particle contain at least 50 host-derived cellular proteins, almost 50% of which are tegument proteins. At least 13 of the host-derived cellular proteins are potentially incorporated into the virions, which may serve specific and auxiliary roles in viral morphogenesis. Although there is no evidence for the presence of cellular-derived host proteins in MdSGHV, the derivation of the viral envelope during the cytoplasmic envelopment process implies incorporation of a complex of host proteins and lipids.

Host Range

Tsetse fly is the only known natural host for GpSGHV, in which the virus predominantly causes chronic asymptomatic (covert) infections. GpSGHV is highly specific to tsetse species, and there is no evidence for its potential infection or replication of heterologous hosts such as the housefly. The susceptibility of tsetse flies to GpSGHV infections differ widely amongst different tsetse species, of which *G. pallidipes* is the most susceptible. There is evidence for the existence of at least 15 GpSGHV haplotypes whose prevalence differs spatially and genetically among different wild populations of tsetse flies in East, Central, and West Africa.

The common housefly (*M. domestica* L.) is the natural host for MdSGHV in which the virus causes only acute symptomatic (overt SGH symptoms) infections. Under laboratory conditions, MdSGHV can infect other insects such as the obligate hematophagous stable fly (*Stomoxys calcitrans*), the autumn housefly (*Musca autumnalis*), and a larval predator of the housefly, the black dump fly (*Hydrotaea aeneascens*). Although MdSGHV is incapable of inducing the diagnostic overt SGH symptoms in other insects, the virus does significantly affect ovarian development and fly mortality in the stable fly and black dump fly. These observations suggest that MdSGHV may reside asymptotically in other muscids as alternative or reservoir hosts. It is however unknown whether these alternative hosts can transmit infectious viral particles to healthy conspecifics under field/natural conditions. MdSGHV also fails to infect or replicate in the tsetse flies when virus suspensions are injected into the flies.

Pathogenesis and Tissue Tropism

All SGHVs induce the same gross pathology (i.e., SGH symptoms) in their respective host insects (adult stages), but the cytopathologies are distinct for each genus (**Fig. 3**). The SG pair are equally affected, swollen up to four times or higher than their normal size, and the enlargement typically covers the entire length of the distal regions of the glands. The precise mechanism(s) underlying the development of SGH symptoms are unknown. In tsetse flies, GpSGHV significantly alters the synthesis of host proteins, notable of which are proteins associated with blood feeding, immunity, cellular proliferation, homeostasis, cytoskeletal traffic and regulation of protein turnover.

Fig. 3 Pathogenesis and the main structural/morphological features of SGHVs. The infected salivary glands (SGs) are swollen up to four times or higher than their normal sizes (A and D). MdSGHV induces hypertrophy (i.e., enlargement of both cytoplasm and nucleus of SG cells) (B), while GpSGHV induces hyperplasia (i.e., enlarged, multi-layered cytoplasm of SG cells; the nucleus is not enlarged) (E). The MdSGHV and GpSGHV particles are shown in panels C and F, respectively. The nucleocapsid core (nc), tegument (tg) and envelope (en) structural components of GpSGHV particle are shown in the inset of panel F. Scale bar in C is 300 nm. Adapted from. Kariithi, H.M., Meki, I.K., Boucias, D.G., Abd-Alla, A.M.M., 2017. Hytrosaviruses: Current status and perspective. *Current Opinion in Insect Science* 22, 71–78. doi:10.1016/j.cois.2017.05.009. (with permission).

Infections of non-SG tissues by the SGHVs is associated with various pathological effects including reproductive dysfunctions, infertility in the females and distorted mating behaviors. These effects are more apparent in flies that exhibit overt SGH symptoms, and the characteristics of the pathologies are distinct for each genus (see below).

Pathogenesis in the Salivary Glands

In the tsetse fly, GpSGHV causes SGs hyperplasia, whereby the cytoplasmic (but not nuclear) compartments of the infected cells are enlarged. The SG cells become multi-layered (Fig. 3) and are capable of replicating. The cellular proliferation is thought to be part of the host's responses to GpSGHV infections, which result from virus-induced reprogramming of differentiated SG cells. Notably, only *G. pallidipes* exhibits overt SGH symptoms, and even in this species, overt SGH symptoms is an exception rather than the rule. Other tsetse species harbor only chronic asymptomatic GpSGHV infections, without any notable host's fitness cost (development and survival). The mechanism(s) underlying the switch from asymptomatic to symptomatic infection states are currently unknown, but it is suspected that certain host's and/or viral factors, and host's microbiota communities influence development of overt SGH. When adult flies are artificially (hemocoelic) injected with GpSGHV suspensions, overt SGH symptoms do not develop in the same parental generations, rather the symptoms develop in the F₁ progenies produced by the virus-injected mothers.

In the housefly, MdSGHV causes SG hypertrophy whereby both the cytoplasmic and nuclear compartments of the infected gland cells proliferate, but the SG cells are incapable of dividing. Unlike in the case of GpSGHV, within 3 days post infection, MdSGHV induces overt SGH symptoms in 100% of the infected individuals (i.e., the virus does not infect asymptotically). Additionally, older adult houseflies show increased resistance to MdSGHV infection, which is partially attributed to the maturation of the PM barrier in older flies.

Pathogenesis in Other Host Tissues

In tsetse flies, overt SGH symptoms are associated with testicular degeneration, ovarian abnormalities, severe necrosis, and degeneration of germaria, reduction of the development, survival, fertility and fecundity of the flies. The testicular degeneration is characterized by vacuolation of the follicles, thus causing complete shutdown of spermatogenesis. GpSGHV infection also causes disintegration of the accessory reproductive glands of males. Virus infection of tsetse fly tracheal cells and milk glands may cause extensive hypertrophy, but without hyperplasia. Infected milk glands become necrotic, and the reservoir organelles that store the milk secretions are depleted. Virus-induced midgut cellular necrosis impair nutrient assimilation, which, combined with the SG

pathologies, results in starvation of infected flies. A combination of these pathological effects of the virus largely accounts for reduce productivity and collapse of tsetse fly colonies.

In the housefly, MdSGHV replicates rapidly, resulting in complete shutdown of vitellogenesis via blocking the production of sesquiterpenoids. The replication of MdSGHV in the cells of corpora-allata and corpora-cardiaca partially accounts for a shutdown of vitellogenesis. In addition, the ovaries of viremic housefly females are arrested at a pre-vitellogenic stage. MdSGHV infection also alters housefly-mating behaviors, whereby viremic females refuse to copulate when paired with healthy males and viremic males show reduced avidity to initiate courtship with healthy females. Examination of various tissues obtained from flies with overt SGH symptoms under TEM provided evidence for presence of viral particles in multiple other tissues including the crop, midgut lumens, and ovarioles.

Viral Latency

One of the outstanding questions that has emerged in the course of SGHVs research is how GpSGHV is maintained at an asymptomatic state in the tsetse host. Some of the proposed hypotheses include: (1) that the virus may be integrated in the host chromosomes; or (2) may occur as an episome in the nuclei; or (3) persist at a low-level, covert infection in the tsetse fly organs. In all these cases, it appears that GpSGHV is 'under the control' of the host and the question is what type of control is exerted. Southern blot analysis using selected GpSGHV genes as probes did not provide any evidence for integration of SGHVs into host genomes as proviruses.

The predominant asymptomatic GpSGHV infection state is thought to represent either a sub-lethal persistent infection state, or viral latency. During persistent infections, a virus remains in specific cells, whereby progeny virions are perpetually produced at low-levels without excessive damage to the host's cells. During latency, viral genome copies and proteins are present in infected cells for a period of time, but without detectable formation of infectious viral particles. Additionally, depending on the tissue tropism, a virus can cause both persistent and latent infections in the same host concurrently, but in different tissues. Based on its pathobiology during asymptomatic infections, GpSGHV is thought to exist in both persistent and latent infection states at the same time. A persistent infection state in the tsetse SG tissue is supported by the release of low amounts of virus particles ($\sim 10^2$ viral genome copies) via saliva during feeding by an asymptomatic fly. In this state, low virus replication levels does not result in the development of overt SGH symptoms. At the same time, the virus may latently infect non-SG tissues such as the tracheal cells, in which viral DNA is detectable but no transcripts. During viral latency or persistence, only minimal numbers of viral genes are expressed to evade the host's immune system, and the virus does not induce overt SGH symptoms or reproductive dysfunctions as observed during the symptomatic infection state.

A specific RNA interference (RNAi) is one of the possibilities of how GpSGHV latency is maintained in tsetse flies. This possibility was informed by findings from other insect viral systems that have been well studied, in which viruses are under the control of the host's RNAi machinery, particularly the small interfering RNA (siRNA) and micro RNA (miRNA) pathways. Research into this aspect of GpSGHV infection has revealed that the virus provokes an RNAi defense response in *G. pallidipes* as evidenced by significant downregulation of some key genes in the siRNA arm of the RNAi machinery (e.g., *Argonaute*) in symptomatic *G. pallidipes* flies as compared to artificially or naturally-infected, asymptomatic flies. A knockdown of *Argonaute-2* gene led to an increased susceptibility to GpSGHV infection as evidenced by increased viral replication. Additionally, evidence suggests the virus alters the host's miRNA expression profiles in *G. pallidipes* (by targeting the host's immune genes and participate in viral immune evasion).

Transmission and Epidemiology

The transmission dynamics of GpSGHV and MdSGHV are distinct in both wild and laboratory-bred tsetse fly and housefly species, which could be attributed to differences in the hosts' ecologies and life histories.

GpSGHV Transmission Dynamics in the Tsetse Fly

GpSGHV is transmitted both vertically (mother-to-offspring, either trans-ovum or through infected milk gland secretions) and horizontally (fly-to-fly). Horizontal transmission is more prevalent and well documented in tsetse mass-rearing facilities where the flies are fed using an *in vitro* membrane-feeding regime. Under these conditions, up to 10 cages with flies (at average densities of approximately 75 flies per cage) are fed on the same membrane in succession. It is estimated that, during a single 10–15 min feeding event, $\sim 10^{6-9}$ viral genome copies are released via saliva secretions by an infected fly. The viral particles released by infected flies are infectious *per os* to susceptible uninfected flies that feed on the same membrane. Infection of the tracheal system, milk glands, germline cells, nurse cells, and the oocytes of the ovaries, ensures vertical viral transmission to the larvae that develop within the mother's womb (adenotrophic viviparity) and on milk gland secretions. Additionally, GpSGHV is efficiently transmitted to the F_1 progenies produced by intra-hemocoelically injected mothers. These F_1 progenies exhibit overt SGH symptoms, the proportion of which gradually increase from the first to fourth gonotrophic (G) cycles (0%–3% in G_1 , 10%–30% in G_2 ,

40%–60% in G_3 , and 100% in G_4 onwards). Except in *G. pallidipes*, injection of GpSGHV into third-instar larvae of tsetse flies does not lead to the development of overt SGH symptoms in the adults that emerge from the virus-injected larvae.

Some of the maternally inherited tsetse microbiota have been implicated in GpSGHV vertical transmission as evidenced by absence of overt SGH symptoms in the F_1 progenies produced by aposymbiotic mothers. Interestingly, the absence and/or presence of certain microbiota such as *Wolbachia* may influence vertical GpSGHV transmission of the virus. Evidence suggests a causal link between the expression of overt SGH symptoms and microbiota as attested to by the absence of the symbiont in *G. pallidipes* (exhibits overt SGH) and its presence in most other tsetse species (without overt SGH). There is no evidence for the transmission of GpSGHV from father-to-progeny, which could be due to reduced virus transmission rates, rather than to a total failure of transmission.

The mechanisms responsible for the circulation and maintenance of GpSGHV in the wild tsetse populations are unclear. Further, there is no evidence for mechanical transmission of the virus via contacts between flies, mating, or fecal contamination. This limits horizontal transmission as the main mode GpSGHV dispersal amongst wild tsetse populations in the field, especially because tsetse flies are known to aggregate on specific mammalian hosts for blood feeding. When feeding on an animal, tsetse flies create blood pools at the bite sites on their hosts. GpSGHV-infected flies could deposit infectious viral particles via saliva into the blood pools, which would be picked up and infect other susceptible flies. This may facilitate transmission of the virus from fly-to-fly without necessarily replicating in the mammalian hosts. The dynamics of such horizontal GpSGHV transmission probably depends on feeding behaviors of specific tsetse species, their host preferences, feeding regimes and susceptibility to GpSGHV infections. Nevertheless, these factors partially explain the significantly low prevalence of GpSGHV in the wild tsetse populations (0.4%–15%) compared to colonized laboratory populations (almost 100% based on a diagnostic polymerase chain reaction [PCR] method).

MdSGHV Transmission Dynamics in the Housefly

MdSGHV is transmitted mainly horizontally during the gregarious feeding of the houseflies. There is no evidence of vertical or sexual transmission of MdSGHV from mother to the progeny in infected houseflies. During feeding, viremic houseflies release an estimated 10^6 MdSGHV genome copies onto the food substrates, which are infectious and serve as inoculum to infect most ($\geq 65\%$) of the co-feeding healthy conspecifics. When newly eclosed (~ 2 h-old) adult houseflies are force-fed with MdSGHV preparations under laboratory conditions, $\geq 50\%$ of the treated flies display SGH symptoms. Unlike in the GpSGHV-tsetse infection system, MdSGHV-infected houseflies remain infectious until their death. However, dynamics of MdSGHV *per os* infection under a laboratory setting may be different in nature because newly eclosed flies do not imbibe food until after several hours. Within 12–24 h post-eclosion, synthesis of the protective gut PM increases the housefly's resistance to orally-ingested virus. Under laboratory conditions, oral infections of newly eclosed adults with low viral quantities is successful only during the initial six hours post eclosion. Further, oral challenge of housefly larvae with MdSGHV suspensions does not result in detectable SGH symptoms in the adults, implying that MdSGHV is acquired during only the adult stages. This raises the question of how MdSGHV is maintained within wild populations of the housefly.

Recently, mechanical transmission of MdSGHV amongst wild populations of houseflies has been suggested as an alternative route for *per os* transmission. This is thought to be through cuticular-wounding events, which circumvents the PM barrier in the midgut by introducing the virus directly into the fly's hemocoel. The likelihood of the occurrence of the mechanical transmission of MdSGHV is partially supported by the increased activity of male houseflies, which increase cuticular wounding, especially during courtship. Notably, males harbor higher viral titers and prevalence than the females. The mechanical transmission of MdSGHV is also supported by the fact that topical applications of virus preparations to the labellum and spiracular regions of the older housefly adults, which are more likely to be wounded, induces SGH symptoms in 10% and 70% of the flies, respectively.

Diagnosis and Management of SGHV Infections

GpSGHV is presumably introduced into tsetse mass-rearing facilities from asymptomatic field-collected materials (e.g., pupae), or those derived from already existing colonies, that are used to establish new colonies or replenish existing ones. The asymptomatic infections and vertical transmission of GpSGHV allow the spread and long-term maintenance of the virus in the colonies. Undefined stress- and/or genetic-related factors may trigger outbreaks of SGH, which result in fly mortality, reduced fecundity and colony collapse.

Diagnosis

There are no obvious external clinical signs of SGHV infections in both tsetse flies and houseflies. However, in tsetse flies, hyperplastic SGs appear as pale outlines with irregular ridges in the abdomens of male flies. The discoloration is probably due to the extension of gland cells towards the cell lumina, resulting to constricted gland lumens. The enlarged and chalky-white glands are often observed in MdSGHV-infected houseflies. In the case of GpSGHV-tsetse model, a simple, sensitive and reliable non-destructive PCR-based diagnostic assay has been developed, which allows the screening of virus infections in individual live

tsetse flies. For this method, a single intermediate fly leg is excised, followed by DNA extraction, PCR amplification of a conserved viral gene (*odv-e66*), and analysis of the PCR products on agarose gels.

Management

The best option to manage GpSGHV infections in tsetse mass rearing is an integrated approach, which involves two components. The first component, which is referred to as the clean feeding system (CFS), is based on strict sanitation, regular and routine monitoring of virus infections and occurrence of overt SGH symptoms, and quarantine of infected fly colonies. The CFS is a modification of the *in vitro* feeding membrane regime aimed to interrupt horizontal virus transmission within the tsetse colonies, and consists of three feeding rounds. On the same membrane, teneral flies are always fed first, after which the rest of the fly cages are fed in a second feeding round, and finally oldest colony flies are fed last in the third round. This prevents uninfected young colony flies from picking up the virus that may be deposited onto feeding membranes by older infected flies. The second component is the supplementation of blood meals with antiviral drugs (e.g., valacyclovir), which are administered at low doses (non-detrimental to fly's DNA synthesis). Virally encoded thymidylate synthase enzymes convert the drugs into active metabolites, which subsequently block viral replication and thus reduce viral titers and shedding. In practice, CFS breaks the cycles of SGH outbreaks and thus rapidly restores colony productivity (within six months) without additional investments in specialized equipment or reagents. The SGH outbreaks are eliminated by the administration of antiviral drugs, which can be withdrawn in case of undesirable side effects, or development of drug resistance. After withdrawal of the antiviral drugs, CFS protocols alone can reduce viral infections to low levels (i.e., <10% virus prevalence) that do not compromise colony productivity. Overall, CFS is recommended in colonies with low SGH or non-observable SGH outbreaks to prevent any development and outbreaks of SGH symptoms.

Conclusions

The SGHVs are a small group of large dsDNA viruses currently restricted to dipteran insects. However, the detection of virus particles that induce the SGH symptoms in Hymenoptera, and are morphologically similar to GpSGHV and MdSGHV, suggest possibility of more members of the *Hytrosaviridae* family. The majority of the SGHV genes are hypothetical (unknown functions) and have limited or no homologies to known genes in other invertebrate viruses. The pathological differences observed from the SGHVs (MdSGHV vs. GpSGHV, and between different GpSGHV strains) appear to reside in the genetics of both the SGHVs and their respective hosts. The ecologies and the life histories of SGHV hosts may have significantly influenced the SGHVs-host coevolution. The roles of other co-infecting microorganisms, particularly the microbiota, cannot be overlooked. The GpSGHV-induced differential expression of overt SGH symptoms in certain *Glossina* species and not others could be attributed to the host's inherent abilities to mount a robust immune response to counteract the viral infections. It is now evident that, different wild and laboratory-bred populations of tsetse fly species are infected by different lineages of the same GpSGHV virus, even in *G. pallidipes* (the only *Glossina* species known to exhibit overt SGH symptoms). Further, the RNAi is a major contributor to the maintenance of asymptomatic/latent infection state of GpSGHV in tsetse as evidenced by the virus-induced provocation of an RNAi defense response via the siRNA arm of the RNAi machinery, and modulation of the host's miRNA profiles during symptomatic infection state.

Glossary

Endogenous viral element (EVE) Virus-derived DNA sequence in the genome of an organism.

Internal ribosome entry site (IRES) Complex secondary RNA structure that allows translation initiation independent of a 5' cap.

UTR Untranslated region in an mRNA at the 5' or 3' end of an open reading frame.

VPg Viral protein genome-linked attaches to the 5' end of positive strand viral RNA and functions to prime RNA synthesis.

Classification

The family *Iflaviridae* is classified under the order *Picornavirales* (Realm *Ribovira*) and shares a number of important characteristics with other families in that order. Iflaviruses have non-enveloped, icosahedral virions ranging from 22 to 30 nm in diameter (Fig. 1). The virions encase a single copy of a positive sense, single-stranded RNA. The genome is 8–10.5 k nucleotides (excluding the polyA tail) and non-segmented with a polyA tail. Translation occurs directly from the genomic RNA via an internal ribosome entry site (IRES) to produce a single polyprotein. This polyprotein is post-translationally cleaved to generate the structural (capsid) and nonstructural proteins.

The type species of the family *Iflaviridae* is *Infectious flacherie virus* (IFV), and all members of the family as recognized by the International Committee on Taxonomy of Viruses (ICTV; Table 1) belong to the genus *Iflavirus*. The name “ifla” is derived from *Infectious flacherie virus*. Iflaviruses are demarcated by host range and <90% amino acid identity in the sequence of the capsid protein precursor. Based on this, *Deformed wing virus* (DWV) and *Varroa destructor virus 1* (VDV1) with 95% amino acid identity appear to be different isolates of the same species.

An additional 17 unclassified RNA viruses appear to belong to the genus *Iflavirus* on the basis of their genome organization (Table 2).

The diversity of iflaviruses is evident from phylogenetic analysis which shows three major clades (Fig. 2) with no relationship between virus relatedness and host range. The dicistroviruses *Cricket paralysis virus* (CrPV) and *Drosophila C virus* (DCV) group separately from *Perina nuda virus* (PnV) and *Ectopis obliqua virus* (EoV) which in turn distinctly differ from other members of the family.

Virion Structure

The smooth surfaced, icosahedral virions are comprised of four structural proteins; three major capsid proteins (VP1-VP3, ranging from 28 to 35 kDa in size) and a minor structural protein (VP4, 4–12 kDa in size). The virion structure is similar to that of the dicistroviruses, for which VP4 is located on the interior of the capsid and may function to bind genomic RNA within the virion. The icosahedral particles have a $T = 3$ symmetry and are made up of 60 protomers with a basic structure similar to those of mammalian picornaviruses. Low pH promotes genome release from the virion implicating host cell entry via endosomes.

Genome

The primary characteristics of the iflaviruses genome are a non-segmented genome of 8–10.5 kb excluding the 3' polyA tail. The genome is translated into a single polyprotein (Fig. 3). Cap-independent translation of the iflaviruses polyprotein is mediated by an internal ribosome entry site (IRES) within the 5' UTR. The polyprotein is cleaved by the virus-encoded protease. Structural proteins are encoded at the 5'-proximal region while non-structural proteins are encoded at the 3' proximal region of the genome. The structural proteins are preceded by a leader protein (L) of unknown function that is removed from VP2 prior to capsid assembly. The nonstructural proteins are encoded in the order RNA helicase (Hel), a chymotrypsin-like 3C protease (pro), and RNA-dependent RNA polymerase (RdRP) similar to other small RNA viruses. The iflaviruses RdRP has a canonical RGD motif, which is typical for RNA polymerases of positive sense, single-stranded RNA viruses. The genome organization of iflaviruses strongly resembles that of picornaviruses.

The 11.5 kDa VPg protein covalently associates with the 5' of the positive and negative strand viral RNA and may be required to prime RNA synthesis similar to the situation in *Picornaviridae*. The location of sequence encoding the VPg protein has yet to be resolved. The construction of an infectious clone of a *Deformed wing virus* genome provides a useful tool for increasing understanding of iflaviruses biology.

Fig. 2 Phylogenetic relationship between viruses in the family *Ifloviridae* based on RdRP sequences. Dicistroviruses CrPV (*Cricket paralysis virus*), NP_647481.1; DCV, (*Drosophila C virus*), NP_044945.1 were used as outgroups. RdRP sequences were aligned using MAFFT version 7 (Multiple Alignment using Fast Fourier Transform) and phylogenetic analysis was conducted using the maximum likelihood (ML) method with 10,000 bootstraps. Evolutionary distance marker indicates 0.3 substitutions per amino acid position. RdRP sequences used were BbV (*Brevicoryne brassicae virus*), YP_001285409.1; DWV (*Deformed wing virus*), AST47884.1; DcPV, (*Dinocampus coccinellae paralysis virus*), YP_009111311.1; EoV (*Ectopis obliqua virus*), NP_919029.1; IFV (*Infectious flacherie virus*), NP_620559.1; LdIV1 (*Lymantria dispar iflavirus 1*), YP_009047245.1; NLHIV1 (*Nilaparvata lugens honeydew virus 1*), YP_009505599.1; PnV (*Perina nuda virus*), NP_277061.1; SBV (*Sacbrood virus*), ATA66298.1; SBPV (*Slow bee paralysis virus*), ADI46683.1; SelV1 (*Spodoptera exigua iflavirus 1*), YP_004935363.1; SelV2 (*Spodoptera exigua iflavirus 2*), YP_009010984.1.

Fig. 3 Genome organization of viruses within the family *Ifloviridae*. The genome encodes a single polyprotein with structural proteins (VP1 to VP4) toward the N-terminus, and nonstructural proteins (helicase, protease, RNA-dependent RNA polymerase) toward the C-terminus. An internal ribosome entry site (IRES) in the 5' untranslated region (UTR) allows for translation directly from the genomic RNA. A covalently linked protein, VPg is present at the 5' end of the genome. The polyprotein produced on translation of the single open reading frame, is auto-catalytically cleaved to generate the individual structural and nonstructural proteins. There are two systems for naming of iflavirus structural proteins, based on genome position and sequence identity, or on size or molecular mass. The system used by the ICTV based on molecular mass is adopted here.

Life Cycle

Ifloviruses have been isolated from only arthropods (**Table 1**) with host ranges limited to one or a few closely related species. Ifloviruses may be vertically and / or horizontally transmitted. For example, DWV is vertically transmitted from queen honey bees to workers and drone progeny, but may also be transmitted from worker to worker either directly through food exchange, or indirectly via the *Varroa* mite. In the latter case, virus is released directly into the body cavity of the honey bee.

Epidemiology

Analysis of the incidence and distribution of honey bee viruses highlighted the dynamic nature of virus infection across hives, locations and seasons. The *Varroa* mite plays a key role in changing the viral landscape with increased DWV prevalence and titer, and selection of a subset of viral variants. Co-infection of a host by ifloviruses and viruses from other families is typical.

Clinical Signs

Iflaviruses are transmitted primarily on ingestion of contaminated diet. Many iflaviruses infect the host persistently without inducing disease symptoms. These viruses are transmitted vertically, which is characteristic of covert, persistent or chronic infection. There are several exceptions to this however with viruses resulting in symptomatic infections including discoloration, diarrhea, developmental abnormalities and death of the host.

Infectious flacherie virus infects mainly the goblet cells in the midgut epithelium of the silkworm and results in accumulation of fluids known as the flacherie phenotype. This flacherie disease causes diarrhea and results in significant losses to the sericulture industry in China and Japan. The flacherie phenotype is also observed on infection of other lepidopteran species by other iflaviruses. In addition fluid accumulation under the skin affects honey bee larvae infected with *Sacbrood virus* resulting in fatal sacbrood disease.

Iflaviruses of the honey bee have received particular attention as a result of research into global honey bee declines. Viral infection (by DWV in particular) is exacerbated by the presence of the Varroa mite, which vectors viruses and weakens the honey bee thereby reducing anti-viral defenses. At high titers, DWV impairs honey bee development, resulting in insects with deformed wings that are unable to fly. DWV can also affect learning behavior and aggression, in addition to lifespan.

Pathogenesis

Iflaviruses replicate in the cytoplasm of host cells and can be observed as crystalline arrays of virions ([Fig. 1](#)). Virus-induced vesicular structures appear to play an important role in virus replication, similar to other picornaviruses. The impact of replication on host cell macromolecular synthesis has not been established for members of this family. Disease manifests when viral titers reach high levels. Information on the manner of disease development is currently limited.

Diagnosis/Detection Methods

Serological methods such as western blot and enzyme-linked immunosorbent assay (ELISA) can be used for detection of viral proteins. Iflaviruses (with the exception of DWV and VDV1 which are viruses of the same species) are serologically distinct, with no serological relationships between family members.

Reverse transcriptase-polymerase chain reaction (RT-PCR) with primers based on unique genome sequences provides an accurate and specific approach for detection of viral sequence. The use of multiple primer pairs is recommended to reduce the likelihood of viral sequence resulting from endogenous viral elements, rather than complete viral genomes. RT-PCR can also be used for detection of negative strand RNA (indicative of virus replication) provided that the appropriate controls (including positive sense RNA) are included. Quantitative PCR (RT-qPCR) can be used for determination of virus titer (genome equivalents) with reference to an appropriate viral sequence standard. A high viral titer would indicate virus replication in a given species, rather than virus that may be associated with an insect, on the surface or in the gut for example.

Cell lines that support replication are available for some iflaviruses, including DWV, PnV, and *Lymantria dispar virus 1* (LdIV1). The availability of such cell lines will facilitate further study of the biology of this virus family.

Prevention

Maintenance of virus free insect colonies and cell lines in isolated, clean facilities is recommended. Management of the Varroa mite in honey bee colonies is essential for preventing escalation of viral titers to potentially damaging levels. Colonies with enhanced hygienic behavior are better able to survive in the presence of Varroa mites.

L Late gene transcription.

NCLDV Nucleocytoplasmic large DNA viruses, a non taxonomic grouping of large DNA viruses that replicate exclusively in the cytoplasm, or like iridoviruses, in both the cytoplasmic and nucleus.

Introduction

Iridovirids, a generic designation for members of the family *Iridoviridae*, are nucleocytoplasmic large dsDNA viruses (NCLDVs) that infect both invertebrates (IIVs) and ectothermic vertebrates (Vertebrate Iridoviruses, VIVs). Infections may be asymptomatic or range in severity from minor reductions in host fitness to systemic disease and large-scale mortality.

Currently, Iridovirids are classified according to virion particle size, host preference, presence of a DNA methyltransferase gene, GC content and phylogeny based on the amino acid sequence of the major capsid protein (Table 1).

Although new iridovirids are continuously being discovered, the genomes of only a limited number of IIVs have been sequenced, and thus, it is hard to precisely quantify or estimate the genetic heterogeneity and variability within each genus. Additionally, it is still not clear what type of information or criteria would be sufficient to determine whether newly discovered iridovirids represent new species or are just variants or strains.

The advent of phylogenetic analysis based on complete genome sequences now provides a superior method of differentiation and classification, (Fig. 1), and using pan-genomic data, which needs the raw sequencing data of the available complete genomes, might very well advance the analysis of viral phylogenies, which may ultimately lead to the development of new criteria for virus classification in general.

Classification of Iridovirids

The invertebrate iridoviruses belong exclusively to the *Betairidovirinae* subfamily of the Family *Iridoviridae*. This subfamily consists of three genera, *Iridovirus* with two species, including the type species *Invertebrate Iridovirus 6*, *Chloriridovirus* with 5 species including the type species *Invertebrate Iridovirus 3* and recently *Decapodiridovirus* with a single species, the type species *Decapod Iridovirus 1*.

There are 26 core genes present in all 45 iridovirid genome sequences, forming four clades. Three clades for each of the vertebrate-infecting genera (*Ranavirus*, *Lymphocystivirus* and *Megalocytivirus*) and one clade for the invertebrate iridoviruses, recently split into three genera (*Iridovirus*, *Chloriridovirus* and *Decapodiridovirus*). Due to the independent monophyletic origins of these vertebrate and invertebrate iridoviruses the subfamilies, *Alphairidovirinae* and *Betairidovirinae* are now recognized.

The currently accepted approach for iridovirid taxonomy is to use the conserved iridovirid genes (26 genes) in phylogenetic reconstructions. The criteria distinguishing taxa for Subfamilies are based on primary host species (i.e., vertebrate vs. invertebrate) and methylation content.

Genera are distinguished by principal host species, sequence-based phylogenetic analysis and sequence identity, with members of different genera displaying <50% sequence identity among a concatenated set of 26 core genes. Species share >95% sequence identity within the set of 26 core genes, phylogenetic relatedness, a co-linear gene order, and similar genome size ($\pm 10\%$) and

Table 1 Comparison of *Betairidovirinae* genera based on their different qualities

Genera	Virion size	Hosts	GC content	DNA methylation
<i>Iridovirus</i>	120–130 nm	arthropods, particularly insects	29%–32%	Absent
<i>Chloriridovirus</i>	180 nm	Diptera with aquatic larval stages, mainly mosquitoes	48%	Absent
<i>Decapodiridovirus</i>	158 nm	Crustaceans	34.58%	Absent

Fig. 1 Complete iridovirid genome sequences based on RAxML Maximum likelihood phylogeny of family *Iridoviridae* as described in Ince, I.A., Özcan, O., Ilter-Akulke, A.Z., Scully, E.D., Özgen, A., 2018. Invertebrate iridoviruses: A glance over the last decade. *Viruses* 10, E161.

G + C content. Although these criteria provide a rationale for the current taxonomy, they are rather poorly defined in terms of assigning new members to iridovirids.

The genomes of many iridovirids have now been sequenced completely, and phylogenetic reconstructions based on complete genome sequences or genome methylation patterns may provide additional resolution when compared to approaches that use only a subset of genes.

Morphology and Composition

IIV-6, formerly called Chilo Iridescent virus, is the most studied invertebrate iridescent virus (IIV). The 212 kbp IIV-6 genome is packed into an icosahedral capsid with a $T = 147$ lattice. The virion is comprised of four concentric domains: an outer membrane derived from the plasma membrane of host in the virions that are released by budding, a proteinaceous capsid layer, an intermediate lipid membrane with associated polypeptides and a DNA-protein core (Fig. 2). Initially measured at 120–130 nm diameter in ultrathin sections, CryoEM and 3D image reconstruction showed a maximum diameter of 185 nm including fibrils emanating from the surface of the virion.

IIV-6 Persistence and Sensitivity to External Factors

IIVs are highly stable in water, but dry soil rapidly inactivates the infectivity of IIV-6. IIV-6 is thermolabile and can be rapidly inactivated once temperatures rise above 55°C. Furthermore, solar UV light and ultraviolet radiation reduces IIV-6 infectivity, especially in aqueous habitats. Exposure to various solvents and enzymes can also impact IIV-6 infectivity, and sensitivity exists both in cell culture and whole insects. In addition, differences in sensitivity to suspensions, based on whether the assay was performed in cell culture or in whole insects, were observed. Notably, when the IIV-6 lipid bilayer was disrupted, the virus was still capable of infecting cultured cells, but not insect larvae when the inoculum was injected into the haemocoel.

These observations highlight the need for studies on the role of the lipid component of the virus (1) in the process of entry (2) host specificity in different hosts and cell lines. This may also explain the observed differences in sensitivity to organic solvents and enzymes documented between vertebrate and invertebrate viruses.

Host Range and Pathology

The host range of IIV-6 includes over 100 insect species belonging to six orders; Coleoptera, Diptera, Hemiptera, Hymenoptera, Lepidoptera and Orthoptera. Additionally, IIV-31 can infect several different isopod species, as well as Drosophilidae. Iridovirid-like particles have also been detected in marine invertebrates. Patent infection with IIV turns the host an iridescent blue and is mostly considered lethal. However, (inapparent) infections are more common, reducing the reproductive capacity and longevity of adult hosts. In some cases, the link between viral presence and mortality is obscure.

For instance, a link between co-infection of *Nosema* species and IIV-6 with insect mortality was suggested but subsequent studies failed to find a significant correlation between IIV-6 and colony collapse disorder in the USA.

IIV-6 can be propagated in nineteen different insect cell lines, with varying levels of susceptibility. In some insects, extracellular host factors may influence viral infectivity and not all cell lines derived from susceptible hosts can be infected with IIV-6. Interestingly, reptiles and amphibians fed IIV-infected insects appear to become infected and invertebrate iridovirus (IIV-6) propagation has also been achieved in some poikilothermic vertebrate cell lines. Intraperitoneal injections of large doses of native or ultraviolet-irradiated IIV-6 were lethal to frogs and mice, while heat- or antiserum-inactivated IIV-6 had no lethal toxicity.

Vertebrates can become infected with IIVs and lethality was observed under laboratory conditions and at high doses, but natural infections are rarely symptomatic or lethal, suggesting that IIV replication is more limited in vertebrate hosts and that the host immune system is able to inhibit viral replication.

Mass produced feeder insects might be a source of viral diseases for reptiles and amphibians kept as pets. However, large-scale IIV outbreaks have not yet been observed.

In vertebrate and invertebrate hosts, IIV-6 infection causes different immune responses. In invertebrates, autophagy and/or apoptosis may not be a typical host response to IIV-6 e.g., *Drosophila*. IIV-6 encoded proteins interfere with insect RNAi immune responses while the JAK-STAT pathway does not provide immunity against an IIV-6 infection.

In vertebrates IIV-6, like many other DNA viruses, can induce a type I IFN-dependent antiviral response in mammalian cells, which is likely triggered by a cytosolic sensor upon viral dsRNA recognition, which is known to be produced in the course of IIV-6 transcription.

Overall, studies suggest that IIVs can occasionally cross-infect certain vertebrates, but that their immune systems may be able to inhibit replication under natural conditions, reducing or preventing symptoms. Another possibility is that IIVs do not replicate productively in ectotherms and thus do not result in disease.

Genome Organization and Codon Usage

The IIV-6 genome consists of a single linear 212,482 bp dsDNA molecule with 28.63% G + C content. Compared to other animal viruses, the IIV-6 genome has a unique arrangement, with circular permutations and terminal redundancies that cause variations in the number of direct terminal repeats during DNA replication and genome packaging. While the coding capacity of the genome was estimated initially at 215 non-overlapping open reading frames (ORFs), the total number of ORFs rises to 468 when both non-overlapping and overlapping ORFs are considered. However, also taking overlapping ORFs into account is still a point of debate.

Importantly, gene transcripts of iridovirids show no evidence of introns, and viral mRNAs lack poly(A) tails. However, biochemical and in silico evidence suggests the existence of viral microRNAs (miRNA) that might modulate viral gene expression. In addition, unlike VIVs, apart from IIV-3, IIVs do not encode a DNA methyltransferase except for SGIV. In silico prediction of the methylation sites of 50 iridovirid genomes has demonstrated that there is a clear distinction in methylation patterns between IIVs and VIVs, except for IIV-3 from IIVs and SDDV and LCDV-1 from VIVs, which have an as yet unclear phylogenetic status.

To date, 26 core genes have been identified in both IIVs and VIVs. They have been linked to virus replication, gene transcription, protein structure and nucleocapsid assembly. The rest of the encoded proteins may have roles in virus-host interactions, hijacking of host cell machinery and establishment of viral infection.

Virion Proteins

Virion proteins have been identified for IIV-1, IIV-2, IIV-6, IIV-9, IIV-22 and IIV-25. However, we have observed that the different experimental settings in these studies do affect the resolution of the gel analyses and thus influence previous results and comparisons.

More recently, a comprehensive proteomic analysis (LC-MS/MS) detected 54 proteins in IIV-6. Possible functions of fifteen of the putative ORFs were inferred to be: serine-threonine kinase, dual specificity protein phosphatase, DNA polymerase (viral) N terminal domain, carboxy terminal domain phosphatase, ribonuclease III, tyrosine protein kinase, cathepsin, DNA-binding protein, protein disulphide isomerase, lysosome associated membrane glycoprotein, and a ranavirus enveloped protein homolog. The remaining 39 proteins lacked similarity to any other annotated viral proteins and should be investigated further.

Genomic analysis of IIV-9 identified 191 predicted genes, with 20% of its repeated sequences located mainly within the coding regions. 97 of 211 IIV-6 genes have detectable orthologs in IIV-9, whereas 108 out of 191 IIV-9 genes have orthologs in IIV-3.

Phosphorylation reactions represent common host responses to iridovirid infection. During IIV-6 infection, increased phosphorylation of the ribosome associated proteins in the early phase of the infection cycle requires the expression of the viral genome. However, phosphorylation events were observed in ribosomal proteins when permissive cells were infected with UV-irradiated IIV-6, suggesting that increasing phosphorylation reactions were likely a host cell response rather than being related to an expression of the viral genome.

Iridovirid genomes contain multiple genes coding for kinases and phosphatases, regulators of protein activities over the course of the infection. Although kinases and phosphatases are among the most abundant proteins, it is challenging to assign functions to these enzymes without expressing them individually in cell culture, making knock-out viruses, unravelling their subcellular localization, or identifying the protein targets that are specifically phosphorylated. One of the viral kinases of IIV-6, using a purified serine/threonine protein kinase 389L (also called iridoptin) was found to induce apoptosis in insect cells but it remains uncertain whether this is a virion associated protein kinase or not.

The functions of many of these viral kinase enzymes remain to be determined however some significant successes have been achieved with nucleoside analogues which are “activated” by phosphorylation by viral and/or host-cell nucleoside kinases, the final target being principally the viral polymerase. Hence, they represent possible new targets for antiviral therapy. Targeting viral polymerases would serve as a safe model system for example in areas like fish farming to develop viral disease mitigation strategies, as kinases play crucial roles in guaranteeing successful viral infections.

Furthermore, virally coded kinases present apoptotic features which could be candidates for developing pest insect controlling agents via generation of transgenic crops with using viral kinases showing pest insect specific toxicity.

Viral Entry, Replication, and Release Strategy

Iridovirids undergo nucleocytoplasmic replication. Initially, the virus attaches to cell surface receptors and the virus is engulfed by the host cell via clathrin-mediated endocytosis or macropinocytosis in a pH-dependent manner. IIV-6 ORF 096L is proposed to act as an insect cell adhesion molecule (CAM) which may facilitate “fusion” between the virus shell and the cellular membranes, or possibly between the internal lipid membrane and cellular membranes. Following the entry into the host cell, immediate early and delayed early transcripts are synthesized. These transcripts encode proteins that are crucial for viral DNA replication and expression of late genes. Then, newly synthesized viral DNA is translocated from the nucleus to the cytoplasm where a second stage of viral DNA replication results in the formation of DNA concatemers (Fig. 3). Late viral transcripts are synthesized by a viral encoded RNA polymerase that has not yet been identified in IIVs. However, there are ORFs with homology to RNA polymerase II indicating that IIVs likely encode a unique viral transcriptase.

Evidence from IIVs and VIVs suggests that a virus-encoded transcriptase synthesizes late viral messages. For example, knock down of the large subunit of the viral transcriptase of SGIV eliminates late protein synthesis.

When replicated DNA reaches the cytoplasm, it forms large concatemers which eventually serve as “feedstock” for packaging of virions. The underlying mechanism is not yet understood. Progeny virions accumulate in large paracrystalline arrays, or egress from the cell by either budding or cell lysis. Viral particles are released from host cells either by budding from the host cell membrane or together with mature virions from infected cells via lysis. (Fig. 3).

The specific classes of lipids in the virion structure can influence virus infectivity. Besides, changes in host cellular lipid composition associated with cell proliferation, apoptosis, cellular stress and viral infection can also occur during viral replication, impacting the virus’ ability to infect its hosts.

Fig. 3 Schematic representation of iridoviral replication. This figure was obtained from the 10th report of ICTV with permission Ince, I.A., Özcan, K., Vlak, J.M., van Oers, M.M., 2013. Temporal classification and mapping of non-polyadenylated transcripts of an invertebrate iridovirus. *Journal of General Virology* 94 (1), 187–192. Chinchar, V.G., Duffus, A.L.J., 2019. Molecular and ecological studies of a virus family (Iridoviridae) infecting invertebrates and ectothermic vertebrates. *Viruses* 11, 538.

Transcriptional Regulation

In IIV-6 infected cells, viral transcription occurs in a regulated temporal gene expression cascade: as immediate-early (IE), delayed-early (DE) and late (L). However, some IE and DE transcripts are still present during the L-stage, and no meaningful correlation has yet been identified between transcription and the prevalence of particular proteins during the course of infection.

A quantitative proteomic study provided detailed information about the kinetics of IIV-6 viral protein levels, showing that the transcripts belonging to the IE class are involved in mainly nucleoside metabolism, blocking host cell apoptosis, post-translational protein modifications and transcriptional activation of DE genes.

The DE genes function as viral DNA polymerases, protein kinases, and transcriptional activators of late genes. The major capsid protein MCP (274L), one of the most abundant proteins in IIV-6, was expressed with other late class transcripts.

The way viral transcriptional regulation is regulated in different target hosts is yet to be investigated.

Promoter Elements and Transcriptional Regulation

It is difficult to conclusively identify promoter elements that regulate the temporal expression patterns of iridovirid genes. A very limited number of studies identified motifs in putative promoter regions that may be important for transcriptional regulation.

IIV-6 virion proteins are likely able to either directly or indirectly activate the promoters to trigger transcription of some/ a few IE genes. Assays confirm that without virion proteins the promoters remained inactive even though the reporter plasmid constructs carrying these promoters were transfected.

Interestingly, DNAPol, helicase, and mcp transcripts of IIV-6 lack polyA tails, and clear polyadenylation signals downstream of these three IIV-6 ORFs were not found.

To identify the transcription termination signals of IIV-6 genes, ligation-based amplification of cDNA ends was used, showing that about half of all IIV-6 genes contained complementary TAATG and CATTA motifs in the 3' UTR regions of their mRNAs. These CATTA motifs may be conserved features that enable formation of hairpins which, in the absence of polyadenylation signals, may serve as transcriptional terminators.

Induction/Inhibition of Apoptosis in Infections

The principles and the dynamics of apoptosis in response to iridovirid infection are similar in vertebrates and invertebrates.

During the early stages of infection, host cells trigger apoptotic machinery to impede the cell-to-cell movement of progeny viruses. However, many viruses have evolved mechanisms to protect their progeny viruses from the adaptive immune system, producing anti-apoptotic proteins to enhance the likelihood of spreading to neighbouring cells. At the same time, viruses also contain genes that may stimulate apoptosis, using it to promote viral dissemination to neighbouring cells.

Studies found that initially, expression of early viral gene/s (IE) inhibited apoptosis, which suggests that one or more IE genes likely function as anti-apoptotic factors (e.g., IIV-6 ORF193R, *iap* gene). But IIVs also code for pro-apoptotic factors, which trigger apoptosis at later stages during the infection with the goal of facilitating viral dissemination.

Concluding Remarks

Notwithstanding the above information, knowledge gaps about iridovirus still exist. It is not known which host and/or viral factors trigger viral entry into and replication in host cells, and the regulatory mechanisms of genes expressed at various stages during infection remain uncharacterized and will likely only be answered through using functional genomics. Identifying viral proteins responsible for viral infectivity is essential for developing a genetic recombination system for iridovirids, as iridovirid DNA by itself is not infectious.

A genetic recombination system will expand the utility of IIVs as a model for identifying and characterizing iridovirid genetic factors driving virus-host interactions, impacting host fitness, and influencing immune system response, ultimately helping to limit or prevent disease in aquatic ecosystems, as well as leading to the development of IIVs as biocontrol agents. IIV-6 can be a potential biopesticide, as studies have identified virally coded genes (e.g., viral kinases) possibly linked to host toxicity, which could be exploited as biocontrol compounds.

Additional functional genomics studies and the expansion of genomic resources may lead to the identification of new virulence factors and toxins that could be exploited and engineered for targeted control against certain groups of insects.

Furthermore, virally coded kinases could represent potential antiviral drug targets in areas like fish farming, as they play crucial roles in guaranteeing successful viral infections.

Mesoniviruses (*Mesoniviridae*)

Jody Hobson-Peters and Daniel Watterson, Australian Infectious Diseases Research Centre, School of Chemistry and Molecular Biosciences, The University of Queensland, St Lucia, QLD, Australia

Classification

The *Mesoniviridae* is a new family of positive sense single-stranded RNA viruses belonging to the order *Nidovirales*. The *mesonivirus* genome is organized similarly to other nidoviruses and its size of approximately 20–21 kb falls intermediately between those of the large nidovirus families (*Coronaviridae*, *Roniviridae*: 26–32 kb) and the small nidoviruses (*Arteriviridae*: 13–16 kb), prompting the name – *mesos* meaning “in the middle” in greek and “ni” referring to nidovirus. Indeed, the *mesoniviruses* represent an evolutionary bridge across a large gap in RNA genome size. Similar to other members of the order, the enveloped *mesonivirus* virions are often observed with projections, at times with large globular heads attached to low density stalks. Mesoniviruses have no known disease association and host range analysis indicates that their replication is restricted to mosquitoes and that they are unable to replicate in vertebrate cells in culture. Mesoniviruses have been isolated from a variety of mosquito species collected from diverse geographical locations, suggesting that these viruses are likely to be very common in mosquito populations. However, most of the *mesonivirus* species have been isolated from *Culex* spp. mosquitoes (Table 1).

Current taxonomy for the *Mesoniviridae* family categorizes the viruses into a single genus, *Alphamesonivirus*, within the subfamily *Namcalivirus* (ICTV, 2018). Within eight subgenera, there are nine species designated *Alphamesoniviruses* 1–9 (Table 1). These assignments were based on genomic sequence analysis using the computational comparative genomics framework DEmARC (DivErsity pArtitioning by hierarchical Clustering) and five replicative protein domains (3CLpro, NiRAN, RdRp, ZBD, and HEL1) that are characteristic of nidoviruses.

The type species, *Alphamesonivirus* 1, accommodates the two closely related viruses Nam Dinh virus and Cavally virus that were both described in 2011 and isolated from various mosquito species collected in Vietnam and Cote d’Ivoire, respectively. New isolates of *Alphamesonivirus* 1 were subsequently cultured from mosquitoes collected in Australia, Austria, China, Indonesia, Mexico, Thailand, and U.S.A (Table 1). Literature suggests that *Alphamesonivirus* 1 is the most frequently detected *mesonivirus* across both geographic location and mosquito genera (Table 1).

The remaining 8 classified species are represented by mostly single reports of the species from one country and often isolated from a single genus of mosquito (Table 1). Apart from the isolates of *Alphamesonivirus* 1, only Casuarina virus (*Alphamesonivirus* 4) and Nsé virus (*Alphamesonivirus* 8) have been isolated from multiple genera of mosquitoes.

Three viruses, Yichang, Dianke, and Moumo viruses, remain to be assigned (Table 1). Yichang virus was detected at a frequency of 16.5% from pools of mosquitoes collected in Hubei, in China. Pairwise evolutionary distances (PED) based on the conserved domains of ORF1b indicate that this virus is divergent from those that have already been classified. Several attempts to isolate Moumo virus from pools of mosquitoes collected in Côte d’Ivoire were not successful. However, a sequence fragment of 7985 nt was elucidated and enabled phylogenetic comparison with other *mesoniviruses*.

Using antiserum produced to a mix of *Alphamesoniviruses* 1 and 8, conservation of antigenic sites in the S and M proteins between *Alphamesoniviruses* 1, 5, 8, and 9 was confirmed. The phylogenetic relationship between the four *mesonivirus* species was further supported with cross-reactivity analysis in Western blot using numerous peptide-specific antisera, whereby cross-reactivity was more likely to be observed between those viruses that were more closely related genetically.

Virion Structure

Electron microscopy studies are limited but indicate that *mesonivirus* virions are spherical, enveloped viruses, ranging in size from 50 to 120 nm (Table 1). Only one study has assessed *mesonivirus* particles by cryo-electron microscopy, determining Casuarina virus (*Alphamesonivirus* 4) virions to have a diameter of 65 nm. On the surface of the particles, most *mesoniviruses* carry large club-shaped projections. Cryo-tomographic analysis revealed that these spike-like projections are attached to the virion via a low density stalk and display a globular head, with distinct similarities to the well characterized spikes of the coronaviruses, severe acute respiratory syndrome coronavirus (SARS-CoV) and murine hepatitis virus (MHV) (Fig. 1). The reported size of the projections ranges from 3 to 4 nm for *Alphamesonivirus* 1 through to 15 nm for *Alphamesonivirus* 4, but may be attributable to differences in imaging (Table 1). Studies using *Alphamesonivirus* 4 indicate that these viruses lack a dense nucleoprotein core complex.

Genome

Mesoniviruses have a positive sense single stranded RNA genome with a 5′ cap and a 3′ poly A tail. A feature consistent with other nidoviruses is the organization of the *mesonivirus* genome into discrete ORFs, each encoding separate functional domains. The *mesonivirus* genome encodes seven ORFs, ordered ORF1a-ORF1b-ORF2a-ORF2b-ORF3a-ORF3b-ORF4, which are bounded by

Table 1 Species in the Family Mesoniviridae, Genus Alphamesonivirus

Subgenus	Species	Name identification	Isolation region	Date of mosquito collection	Mosquito species	Titer in C6/36 cells/ml	Particle morphology
Namcalivirus	Alphamesonivirus-1	Cavally virus	Côte d'Ivoire	2004	<i>Culex</i> spp. <i>Aedes</i> spp. <i>Anopheles</i> spp. <i>Uranotaenia</i> spp. <i>Culex vishnui</i> <i>Culex tritaeniorhynchus</i>	10 ^{9.7} TCID ₅₀	120 nm with 12 nm spikes
		Nam Dinh virus	Vietnam	2002	<i>Cx. annulirostris</i> , <i>Cq. xanthogaster</i> , <i>Ae. vigilax</i>		60-80 nm
			Australia	2007 – 2014	<i>Uranotaenia unguiculata</i> <i>Culex quinquefasciatus</i> <i>Culex quinquefasciatus</i>		50-80 nm, 3 nm spikes
			Austria China U.S.A	2016–2017 2004, 2010	<i>Ae. albopictus</i> <i>Culex quinquefasciatus</i> <i>Culex quinquefasciatus</i> <i>Ae. taeniorhynchus</i> <i>Culex pipiens</i>		
		Houston virus	Mexico Mexico	2017 2007/08	<i>Cx. vishnui</i> <i>Cx. tritaeniorhynchus</i> <i>Cx. vishnui</i> <i>Cx. australicus</i> <i>Mosquito pool</i>		55–65 nm
		Bontang Baru virus	South Korea Indonesia	2012 1981			~50 nm
		Ngewotan virus	Indonesia	1981			~50 nm
		Kamphaeng Phet virus	Australia Thailand	2015 1984–85			80 nm
							65 nm with 15 nm spikes
Karsalivirus	Alphamesonivirus-2	Karang Sari virus	Indonesia	1981	<i>Cx. vishnui</i>	10 ¹¹ PFU	80 nm
Karsalivirus	Alphamesonivirus-3	Dak Nong virus	Vitenam	2007	<i>Cx. tritaeniorhynchus</i>	10 ^{8.5} TCID ₅₀	65 nm with 15 nm spikes
Casualivirus	Alphamesonivirus-4	Casuarina virus	Australia	2010, 2006	<i>Cq. xanthogaster</i> <i>Culex annulirostris</i>		
Hanalivirus	Alphamesonivirus-5	Hana virus	Côte d'Ivoire	2004	<i>Culex</i> spp.	10 ^{9.3} TCID ₅₀	120 nm with 12 nm spikes
Ofalivirus	Alphamesonivirus-6	Ofaie virus	Brazil	2010	<i>Mansonia</i> spp.		
Kadilivirus	Alphamesonivirus-7	Kadiweu virus	Brazil	2010	<i>Culex</i> spp.		
Enselivirus	Alphamesonivirus-8	Nsé virus	Côte d'Ivoire	2004	<i>Culex</i> spp. <i>Aedes</i> spp. <i>Anopheles</i> spp. <i>Anopheles</i> spp.	10 ^{8.8} TCID ₅₀	
Menolivirus	Alphamesonivirus-9	Méno virus	Côte d'Ivoire	2004	<i>Uranotaenia chorleyi</i>	10 ^{8.3} TCID ₅₀	120 nm with 12 nm spikes

Unassigned		Moumo virus	Côte d'Ivoire	2004	<i>Cx. nebulosus</i>		65 nm with 5 nm spikes
Unassigned		Dianke virus	Senegal	2012/2013	<i>Anopheles</i> spp. <i>Culex</i> spp. <i>Aedes</i> spp. <i>Mansonia</i> spp.		5 nm spikes

Fig. 1 *Mesonivirus particle morphology and spike protein architecture.* Left and middle panels: Negative stained transmission-electron micrographs of Nam Dinh virus (Alphamesonivirus 1) and Casuarina virus (Alphamesonivirus 4) particles. Spikes on the virion surface are highlighted with white arrows. Right panel: Proposed *mesonivirus* virion architecture, with trimeric spike proteins (S) projecting from an ordered M protein/lipid bilayer support. Scale bars indicate 50 nm. Images produced by Dr Daniel Watterson, The University of Queensland, Australia.

Fig. 2 *Mesonivirus genome organization.* Schematic representation of the typical genome of *mesoniviruses* using Cavally virus (Alphamesonivirus 1) as the representative. The open reading frames are shown by boxes. In ORFs 1a and 1b, the functional domains (3C-like serine protease (3CLP), RNA-dependent RNA polymerase (RdRp), zinc-binding (Z), helicase (Hel), exoribonuclease (ExoN), N7-methyltransferase (NMT) and 2'-O-methyltransferase (OMT)) are shaded gray and the ribosomal frame shift (RFS) element is shown. ORF2a encodes the S glycoprotein, which is cleaved (indicated by inverted triangles) to generate S1, S2 and an uncharacterized N-terminal fragment. An alternative ORF (2b) is encoded at the N-terminal end of ORF2a and expresses the N protein (colored in orange). The putative membrane protein is encoded by ORF3a. The function of the predicted protein encoded by ORF3b is not known and the putative ORF4 is indicated by a solid black rectangle.

5' and 3' untranslated regions (Fig. 2). The two largest ORFs, ORF1a and ORF1b, are located at the 5' end of the genome and overlap by a few nucleotides, with translation regulated by a ribosomal frameshift motif (RFS), with the sequence GGAUUUU, allowing the two respective polypeptides, pp1a and pp1ab, to be expressed. A second possible RFS also exists between ORFs 3a and 3b.

Downstream of ORF1b are multiple smaller ORFs that code for the virion proteins. These ORFs at the 3' end of the genome are expressed from two subgenomic RNAs, as confirmed by Northern blot. Transcription regulating sequences (TRSs) have been identified which are predicted to control the synthesis of the subgenomic RNAs.

ORF1a/ORF1b

ORFs 1a and 1b code for the key replicative enzymes. The replicase genes include conserved functional domains that are present in *mesoniviruses* and larger *nidoviruses*. The viral 3C-like chymotrypsin-like protease (3CL^{pro}) domain is flanked by transmembrane domains (TM) and is translated from ORF1a (Fig. 2). Consistent with the role of 3CL^{pro} for other *nidoviruses*, studies with Alphamesonivirus 1 3CL^{pro} have confirmed the autocatalytic activity of 3CL^{pro}, as well as its role in the processing of the enzymes encoded by ORF1b (Fig. 2). However, the *mesonivirus* 3CL^{pro} does feature distinct substrate specificities in comparison to other *nidoviruses*. Another attribute of some *mesoniviruses* is that the N terminus of ORF1a can be variable in length, due to the presence of large block insertions of up to almost 200 amino acids for some viruses such as Yichang, Karang Sari, and Bontang Baru viruses. Apart from variations on the sequence SKRKKG commonly seen at the termini of these insertions, function of these insertions is unclear.

Encoded by ORF1b are the remaining replicative enzymes – a RNA-dependent RNA polymerase (RdRp), a complex zinc-binding motif (Z) linked to a superfamily 1 helicase (Hel), 3' to 5' exoribonuclease (ExoN), N7-methyl-transferase (NMT) and 2'-O-methyltransferase (OMT) from ORF1b (Fig. 2). As detailed above, these enzymes are processed from the polyprotein by 3CL^{pro} and putative host cell protease(s). NendoU is the only replicase domain not encoded by *mesoniviruses*, but for which is part of the typical constellation of seven conserved domains of other *nidoviruses*.

Of note is the acquisition of ExoN by an ancestral group from which the *mesoniviruses* descended. This facilitated the required increase in replication fidelity, necessary for the evolution of the *coronaviruses*, which boast the largest RNA genome size. It is the presence of conserved functional ExoN and OMT domains within the genomes of *mesoniviruses* and other larger *nidoviruses* which distinguish them from the smaller *nidoviruses*.

Structural Proteins

The structural and accessory proteins are encoded by five ORFs at the 3' end of the *mesonivirus* genome and are translated from subgenomic mRNAs (Fig. 2). Analysis of the *mesonivirus* genome suggests the presence of eight structural proteins, including glycoprotein spike (S protein, S1 and S2 subunits) (ORF2a), nucleocapsid protein (N) (ORF2b), and four membrane-spanning proteins (M protein – p17, p18, p19, and p20) (ORF3a). Protein expression analysis could not detect proteins from ORF3b or ORF4.

The spike protein encoded by ORF2a is translated as a precursor polypeptide, which undergoes post-translational proteolytic processing to form the spike proteins. N-terminal sequence analysis of Cavally virus and Dak Nong virus spike proteins confirmed the processing of the ORF2a peptide by a signal peptidase to create S (p77–80) and a furin-like protease to generate the two spike proteins, S1 (p23) and S2 (p55–57), which share a common N terminus and C terminus with S, respectively. While the signalase cleavage site appears to be relatively variable between the *mesoniviruses*, the furin-like motif is conserved. The S1 and S2 proteins are post-translationally modified by N-linked glycosylation.

The extreme N-terminus of ORF2a translation product has not been detected, either as part of a full-length ORF2a polypeptide, or the signalase-cleaved product and exhibits high sequence variability between the *mesoniviruses*. An alternative ORF (ORF2b) is, however, encoded within this region (Fig. 2). Translation of this ORF results in the production of the putative 25 kDa hydrophilic nucleoprotein.

Immediately downstream of ORF2a are two overlapping ORFs – ORF3a and ORF3b, the former encoding the putative glycosylated membrane (M) protein. In silico analysis of ORF3b proteins suggests features consistent with a class II transmembrane protein, although there is poor sequence conservation and a function of the protein remains to be established. In the 3'-terminal end of the genome, most *mesoniviruses* encode an additional putative ORF (ORF4). While it is not known if ORF4 is expressed in cells and analysis of the putative protein does not yield any indication of possible function, there is a high level of sequence identity at the N-terminal region. Experiments using anti-serum produced to the first 223 aa of ORF2a, and the predicted proteins of ORF3b and ORF4 of Cavally virus did not provide any evidence for the presence of these proteins in virus-infected cells.

Life Cycle

The tropism of *mesoniviruses* is restricted to insect cells, and perhaps only to mosquitoes, although robust analysis for replication in a variety of insect cells is warranted. Numerous in vitro infection studies have been performed on a range of mammalian and avian cell lines to provide evidence that *mesoniviruses* do not replicate in vertebrate cell lines. In mosquito cell culture, the viruses cause varying degrees of cytopathic effect depending on the virus. In the *Aedes albopictus* mosquito cell line, C6/36, *mesoniviruses* replicate to very high titers, frequently exceeding 10^8 infectious units per ml (Table 1). The replication in C6/36 cells is also rapid. Within 24 h, 10^9 to 10^{10} RNA copies/ml can be detected in culture supernatant, peaking at 10^{11} RNA copies/ml by 48 h post-infection. The viruses will also replicate readily in cell lines of *Culex* mosquito origin, but to lower titers.

There is evidence for maintenance of insect-specific viruses of other families within the mosquito population via vertical transmission. The detection of Alphamesonivirus 1 RNA in both male and female mosquitoes provides some evidence that *mesoniviruses* are similarly transmitted from the female mosquito to her progeny. The detection of Dianke virus in pools of male mosquitoes further support the likelihood of vertical transmission. However, more studies in this area are warranted. It has been shown that *mesoniviruses* disseminate into the legs and wings of naturally infected mosquitoes and intriguingly the viral nucleic acid in mosquito saliva expectorated onto honey-baited cards was detected. These data suggest that there may be numerous routes of transmission between mosquitoes.

This is an update of J.-H. Leu, J.-M. Tsai, C.-F. Lo, White Spot Syndrome Virus, In Encyclopedia of Virology (Third Edition), edited by Brian W.J. Mahy, Marc H.V. Van Regenmortel, Elsevier Ltd., 2008, doi:10.1016/B978-012374410-4.00776-7.

Glossary

DNA dependent RNA polymerase (DdRp) An RNA polymerase that copies mRNA from a DNA only template.

Homologous repeat (hr) a sequence of DNA with several copies of imperfect palindromes, that are repeated two or more times in the genomes of baculoviruses or whispoviruses.

In situ hybridization (ISH) A technique that uses a labeled complementary DNA or RNA probe to hybridize and detect a specific DNA or RNA sequence in a section of tissue (in situ).

Internal ribosome entry site (IRES) A sequence in mRNA, either at the 5' end or internal between ORFs allowing for translation of a downstream internal ORF in a cap-independent manner.

Microarray A DNA microarray is a collection of microscopic dsDNA or oligonucleotide spots that are deposited on a solid glass slide at high density. Each spot commonly represents a single gene. DNA microarrays use DNA–DNA or DNA–RNA hybridization to perform simultaneous large-scale analyses of the expression levels of the corresponding genes.

RNAi (RNA interference) RNAi refers to the introduction of homologous double-stranded RNA to specifically interfere with the target gene's expression in the cells/organisms. It was originally discovered in *C. elegans*, and is now widely used in many organisms for null mutations. Recent studies suggest that RNAi can be applied in shrimp as well through intramuscular injection of dsRNA.

Introduction

White spot syndrome viruses (WSSVs) cause White spot disease resulting in a major economic problem in worldwide industrial shrimp and crayfish fisheries. They have a wide host range causing lethal diseases in shrimp, prawns, crabs, lobster, crayfish and copepods. The first whispovirus to be documented was called white spot bacilliform virus, now named White spot syndrome virus-CN. As evidenced by earlier names of isolates such as Chinese baculo-like-virus, *Penaeus monodon* non-occluded baculoviruses II and III and white spot baculovirus, these viruses were originally thought to be baculoviruses and were classified with the *Baculoviridae*. However due to unique features in their morphology and phylogeny they were placed in a new family, *Nimaviridae* in 2002.

Taxonomy

The *Nimaviridae* family has a single genus, *Whispovirus*, with a single and type species *White spot syndrome virus*, all taxa names approved by the International Committee on Taxonomy of Viruses (ICTV) in 2002. Mercifully there are no higher orders of classification (Order, Class, Phylum, Kingdom, Realm) for *Nimaviridae*. There is one exemplar virus in the species, white spot syndrome virus CN (WSSV-CN). Thirteen additional viruses are recognized by ICTV, though many more isolates have been characterized. While the etymology of the species name is more self-evident (from white spot syndrome virus), that of the family name relates to the viral morphology not the disease. A distinguishing and unique feature of the whispoviruses is that they have a polar thread-like tail, “nima” in Greek, which gave rise to the family name *Nimaviridae*. Prior to 2002, due to the circular nature of the large dsDNA genome and similarity in morphology to baculoviruses, the white spot syndrome viruses were initially misclassified in the *Baculoviridae* (subfamily *Nudibaculovirinae*, genus *Nonoccluded baculovirus*). However, their unique morphology, genome structure and phylogeny showed they were clearly distinct from the baculoviruses and were deserving of their own *Nimaviridae* family.

Virion Structure and Composition

WSSV virions are enveloped, ellipsoid to bacilliform in shape measuring 70–170 nm diameter and 210–420 nm in length with a rod-shaped nucleocapsid 50–80 nm in diameter and 300–420 nm long (Figs. 1 and 2(b)). One end of the nucleocapsid appears open and flattened and the other end is more rounded. By electron microscopy the nucleocapsids have a distinct pattern of a

Fig. 1 Morphology of WSSV virions (a) intact WSSV virion with tail like extension at the smaller end. (b) WSSV nucleocapsid showing the stacked ring structures made up of two rows of VP664-based globular subunits. From Leu, J.H., Tsai, J.M., Lo, C.F., 2008. White spot syndrome virus. In: Mahy, B.W.J., van Regenmortel, M.H.V. (Eds.), *Encyclopedia of Virology*, third ed. pp. 450–459.

stacked series of about 16 rings, each about 20 nm in thickness and composed of two rows of 12–14 globular units each about 10 nm in diameter. Between the envelope and nucleocapsid is a tegument layer. A thread-like tail, or “nima” responsible for the family name, extends from the narrower end of the virus. WSSV virions have a buoyant density of 1.2 g cm^{-3} and nucleocapsids have a buoyant density of 1.31 g cm^{-3} and are quite stable in pond water, being viable for 3–4 days.

SDS PAGE (Fig. 2(a)) and proteomic analyses have identified about 40 structural proteins ranging from 11 to 664 kDa in size. WSSV virions have a complex SDS-PAGE protein profile (Fig. 2(a)). Early structural protein studies used SDS-PAGE coupled with Western blot analyses and/or N-terminal sequencing of proteins to identify at least six structural proteins. More recent studies have used mass spectrometry to analyze the protein profiles of purified WSSV virions separated by SDS-PAGE and 2-D electrophoresis, and more than 40 structural proteins have now been identified. The major structural proteins are VP664, VP28, VP26, VP24, VP19, and VP15 (Fig. 2(a, b)). VP15 is a basic capsid protein with *in vitro* DNA-binding activity, and it has high homology to the lysine- and arginine-rich DNA-binding proteins of the insect baculoviruses. This protein is therefore thought to be responsible for packaging of the WSSV DNA into the nucleocapsid. VP26, one of five tegument proteins, can interact with nine host proteins including actin, but the importance of this interaction remains unknown. VP26 interacts with beta-integrin to potentially facilitate virus entry, and antiviral proteins such as C-type lectins (MjLecA and LvCTL1) and prohibitins (PHBs). VP19 and VP28 are envelope proteins, and an *in vitro* physical interaction between VP28 and tegument proteins VP24 and VP26 has been reported. VP664, the major capsid protein, takes its name from its calculated molecular mass of 664 kDa. Not only is it the largest protein encoded by the WSSV genome, but it is also the largest viral structural protein ever found. This protein is encoded by the intronless giant ORF (*wssv419*) of 18,234 nt. Immunoelectron microscopy of purified virions has shown that VP664 forms the globular subunits visible in the nucleocapsid ring structures. VP664 antibodies bind to the nucleocapsid but not envelope of purified virions (Fig. 3). In addition to VP15, a very basic DNA binding nucleoprotein, and VP664, the nucleocapsid contains at least four other minor proteins: VP160A (WSSV344), VP160B (WSSV094), VP60B (WSSV474), and VP51C (WSSV364) (Fig. 2(b)).

Neutral lipids, phosphatidylcholine and phosphatidylethanolamine form the major lipids of the envelope, along with the fatty acids stearic acid, eicosapentaenoic acid and docosahexaenoic acid.

Genome and Phylogeny

The nimavirus genome is a large, circular dsDNA (Fig. 2(a)), one of the largest viral DNAs published rivaling that of some phycodnaviruses which range from 154,641 bp for a phaeovirus to 459,984 bp for a prymnesiovirus. There are currently 15 fully sequenced nimavirus genomes accessible from Genbank (Table 1), showing a range in size from 280,591 bp for WSSV-IN-AP4RU from India to 309,286 bp for WSSV-CN01 from China. Note, not included in Table 1 is the genome sequence for WSSV-EG3 (KR083866.1) since it is a duplicate of the WSSV-CN (AF332093) genome and the supporting publication for the WSSV-EG3

Fig. 2 WSSV structural proteins and genome. (a) SDS-PAGE profile of purified WSSV virions. The six major and some minor structural protein bands are indicated. The bands corresponding to two host proteins, hemocyanin and actin co-purified with the virion are also indicated. (b) A proposed schematic diagram to show the WSSV virion structure and the location of some WSSV structural proteins and its DNA. (c) Distribution of 33 WSSV structural protein genes in the WSSV-TW genome. The inner circle shows predicted HindIII restriction enzyme cutting sites. Modified from Leu, J.H., Tsai, J.M., Lo, C.F., 2008. White spot syndrome virus. In: Mahy, B.W.J., van Regenmortel, M.H.V. (Eds.), *Encyclopedia of Virology*, third ed. pp. 450–459.

genome was withdrawn by the authors. Also not included in this table and article are nimavirus-like endogenous genomes found in host genomes.

All genomes have a G + C content of about 41%. Although most WSSV genome sequences are unique, 3% of the genome consists of highly repetitive sequences, which are organized into about nine homologous regions (*hrs*) with the number of repeats of about 250–300 bp within an *hr* varying among isolates and localized to intergenic regions. The *hrs* include a variety of repeats including direct repeats, atypical inverted repeats and imperfect palindromic sequences. Their function in the nimaviruses is unknown but in baculoviruses, *hrs* have been implicated in DNA replication and as enhancers of early gene transcription. Differences in genome lengths have been attributed to various indels, like the insertion of a 1.3 kb transposase sequence in the genome of WSSV-TW and deletions in the WSSV-TH genome and in variations in the number and size of *hrs*.

Fig. 3 Immunoelectron microscopy analysis of purified WSSV virions detected with VP664 antibody followed by gold-labeled secondary antibody. (a) The anti-VP664 antibody specifically binds to the nucleocapsid and not to the viral envelope. (b) Most of the gold particles are localized at the perimeter of the nucleocapsid. From Leu, J.H., Tsai, J.M., Lo, C.F., 2008. White spot syndrome virus. In: Mahy, B.W.J., van Regenmortel, M.H.V. (Eds.), Encyclopedia of Virology, third ed. pp. 450–459.

Table 1 Characteristics of fifteen WSSV isolates and their complete genomes (derived from Genbank as of Aug 31, 2020)

^bFrom archival paraffin embedded tissues of shrimp infected with a China CN95 strain of WSSV.

^cWSSV-CN-PC02 was originally named *Procambarus clarkii* virus. In this review the abbreviation WSSV-CN-PC02 is used to maintain the consensus in the naming of WSSV isolates beginning with WSSV followed by letters indicating its origin (CN for China), Pc for *Procambarus clarkii* and isolate number, 02 since another WSSV-CN-Pc was previously described. Common names: *Penaeus monodon*, Asian tiger shrimp or black tiger shrimp; *Marsupenaeus (Penaeus) japonicus*, Japanese tiger prawn or Kuruma shrimp; *Litopenaeus vannamei*, Whiteleg shrimp; *Procambarus clarkii*, Red swamp crayfish.

By analysis of the 15 current whispovirus genomes using MAFFT alignment, the overall genome sequence identity between genomes is quite high, between 92.44% and 98.91% (Table 2). Despite the overall identities, the genomes separated into two phylogenetic clades (Fig. 4). The most populous clade is clade B including two subclades B1 and B2. For the four isolates in subclade B1, the % identities range from 95.6% to 97.3%, all above 95% for all and their genomes range from 281 to 287 kb in size. The ten isolates within subclade B2 have % identities ranging from 95.28 to 98.91, all above 95%. Genome sizes in this subclade are among the largest and range from 289 to 309 kb. Nevertheless, the % identities between WSSV genomes from subclade B2 compared to genomes from subclade B1 range from 93.97% to 97.33% suggesting they should be part of the same clade B. The single isolate in clade A, WSSV-IN-AP4RU from India, has the lowest level of % identity with any of the other 14 isolates, ranging from 92.44% to 93.62% and has the smallest genome at 280,591 bps. Moreover, WSSV-IN-AP4RU appears to be an earlier genome compared to all the other WSSV genomes. The clades/subclades described here mimic the clusters observed in

the unrooted phylogenetic tree (Fig. 3(b)) and for subclades B1 and B2 mimic the two clusters derived for nine genomes using ClustalW alignment reported by Oakey and Smith (2018).

Both strands of nimavirus DNAs have protein coding genes. For those genomes that appear to be well annotated, whipovirus genomes encode from 150 proteins for WSSV-EC-15098 to 191 proteins, for WSSV-CN-Pc (based on NCBI “Protein” tables) (Table 1). However, for some isolates, identified by “a” in Table 1, the number of proteins is much higher, between 442 for

Fig. 5 Hematoxylin and eosin (HE) staining of tissue section from *Penaeus monodon* cuticular epithelium of eyestalk infected with WSSV. Degenerated cells characterized by hypertrophied nuclei (black arrows) are readily seen. The cells with normal nuclei are also indicated with arrowheads. Scale = 20 μ m. From Leu, J.H., Tsai, J.M., Lo, C.F., 2008. White spot syndrome virus. In: Mahy, B.W.J., van Regenmortel, M.H.V. (Eds.), Encyclopedia of Virology, third ed. pp. 450–459.

WSSV-IN-AP4RU to 904 for WSSV-AU. These very high numbers, considering the genome size, suggest their genomes were over annotated, e.g., including smaller ORFs that clearly overlap larger ones and counting all ORFs even if fully overlapping.

Proteomic and genomic studies have identified genes for at least 48 structural proteins including 31 envelope proteins such as the major envelope proteins VP28 and VP19, five tegument proteins like the major tegument proteins VP26 and VP24 and nine nucleocapsid proteins like the major VP664 component of nucleocapsids and VP15, the major DNA binding protein. A number of nonstructural proteins were also identified. Of the 18 immediate early genes, *ie1*, *ie2*, *ie3*, and *ubiquitin E3 ligase* were identified. Genes for four antiapoptotic proteins (AAP), i.e., AAP1, 2, 3 and 4 were identified. Genes for at least nine enzymes were detected including for thymidylate synthase, protein kinases 1 and 2, a nuclease, DNA polymerase, two ribonucleotide reductases (RR1 and RR2), thymidine kinase/thymidylate kinase and a dUTPase. Given the large size of its genome, it is not surprising to find some additional interesting nimavirus genes including for two anti-melanization proteins, two latency-related genes, and genes for a histone-binding DNA mimic, mitochondria targeting protein and a TATA-box binding protein.

Life Cycle

WSSV replication occurs in the tissues of mainly ectodermal (cuticular epidermis, fore- and hindgut, gills and nervous tissue) and mesodermal (lymphoid organ, antennal gland, connective tissue and hematopoietic tissue) origin but not in tissues of endodermal origin (hepatopancreas and midgut). In the early stage of infection, affected cells display nuclear hypertrophy (Fig. 5), nucleoli dissolution, and chromatin margination, and the central area changes into a homogeneous eosinophilic region. The infected cells then develop an intranuclear eosinophilic Cowdry A-type inclusion, which becomes a light basophilic, denser inclusion separated by a transparent zone from the margined chromatin. The cytoplasm becomes less dense and more lucent. Later in infection, the nuclear membrane is disrupted, causing the intranuclear transparent zone to fuse with the lucent cytoplasm. At the end of cellular degeneration, the nucleus or whole cell disintegrates, leading to loss of cellular architecture. In moribund shrimp, most tissues and organs are heavily infected with the virus, and they exhibit severe multifocal necrosis.

Following infection, the first WSSV-positive signals detected are in the stomach, gills, cuticular epidermis, and connective tissue of the hepatopancreas (Fig. 6). At later stages of infection, the lymphoid organ, antennal gland, muscle tissue, hematopoietic tissue, heart, midgut, and hindgut also become positive. As infection proceeds, the stomach, gill, hematopoietic tissue, lymphoid organ, antennal gland, and cuticular epidermis become heavily infected with WSSV, which leads to serious damage and necrosis and/or apoptosis.

The entire WSSV replication cycle is nuclear and, in an acutely infected shrimp, can be completed within 24 h post infection. WSSV enters susceptible cells via caveola- or clathrin-mediated endocytosis facilitated, in part by the binding of the major envelope glycoprotein VP28 and cell receptors such as integrins α C1qR and Rab7 and a complex of about 11 virion proteins interacting with cell surface chitin-binding protein (CBP) which may also facilitate endocytosis. Several viruses use the Arg-Gly-Asp (RGD) motif to bind to cellular integrins during infection and this cell attachment site signature can be identified in at least six WSSV structural proteins. One of these six structural proteins, VP110 (WSV035), can attach to shrimp host cells, and this adhesion can be blocked by synthetic RGDT peptides, suggesting that the RGD motif in VP110 may play a role in WSSV infection.

Following endocytosis, WSSV travels through endosomes and as a consequence of acidification of the endosomes and the interaction between VP28 and Rab7, the nucleocapsids are released to the cytoplasm. By an unknown mechanism WSSV nucleocapsids enter the nucleus (structurally similar baculovirus rod-shaped nucleocapsids enter nuclei through the nuclear pore

Fig. 6 *In situ* hybridization analysis of WSSV positive cells (arrows) in (a) the integument, (b) the gill, (c) the stomach, and (d) the heart from experimentally infected *Penaeus monodon* at 60 hpi. The infected cells shown here in the heart are connective tissue cells; muscle cells are not usually targeted by WSSV. Scale = 20 μ m. From Leu, J.H., Tsai, J.M., Lo, C.F., 2008. White spot syndrome virus. In: Mahy, B.W.J., van Regenmortel, M.H.V. (Eds.), *Encyclopedia of Virology*, third ed. pp. 450–459.

or uncoat at the nuclear pore, so WSSV might use a similar nuclear entry mechanism). Once in the nucleus, transcription of viral genes can begin. Most virus RNAs are 5' capped and 3' polyA tailed, with no evidence of splicing. Some virion protein genes such as *vp31*, *vp39b*, and *vp11* are arranged in a cluster, producing polycistronic mRNAs which use internal ribosome entry sites (IRES) to regulate their translation. Several IRES elements have been identified, for example upstream of *vp28*, *wsv493* (*icp35*) and across the coding region of *vp31* and *vp39b*. Immediate early gene expression, like that for *immediate early gene 1* (*ie1*), is mediated by host transcription factors and RNAPolIII, initiating a temporal transcriptional cascade consisting of immediate early (IE), early (E), late (L) and very late (VL) phases. *ie1* genes, can be expressed in the presence of cycloheximide indicating their expression relies solely on host factors. The *ie1* promoter is characterized by an upstream TATA-box and binding site for the host transcription factor Sp1. About 16 early ORFs have transactivation activity, presumably assisting in later gene transcription. Structural gene promoters incorporate a degenerate ATNAC motif that could be involved in late gene transcription. Unlike baculoviruses, whispoviruses show no evidence of a viral DNA dependent RNA polymerase (DdRp) and must rely on the host RNAPolIII and host factors. Thus, early viral transcription factors like IE1, IE2 and IE3 might recognize late gene promoters recruiting the cellular RNAPol and transcription factors allowing for late gene transcription.

Viral and host miRNAs may be involved in WSSV infection and latency. For example, *M. japonicus* miR-7 targeted viral *wsv477*, an early gene involved in virus replication and when injected, reduced WSSV copies by 1000 fold late in infection. Studies of WSSV expression identified as many as 89 WSSV miRNAs, the majority in the early phases. Some miRNAs showed tissue specific expression. For example, WSSV-miR-N24 inhibits apoptosis by downregulating host *caspase 8*. WSSV-miR-66 targets viral *wsv094* and *wsv177* and WSSV-miR-68 targets *wsv248* and *wsv309* genes related to latency to virus replication.

Not much is known about whispovirus DNA replication. Nevertheless, the WSSV genome contains several genes identified through homology searches that encode proteins involved in DNA metabolism and replication. These genes include *thymidylate synthase*, *dUTPase*, *ribonucleotide reductases* (*rr1* and *rr2*; two separate ORFs encoding the two subunits), chimeric *thymidylate/thymidine kinase* (TK-TMK), and *DNA polymerase*. The chimeric *thymidylate/thymidine kinase* gene is a unique feature of WSSV, as these genes in other large DNA viruses are encoded in separate ORFs. The enzymatic activities of dUTPase, ribonucleotide reductase, and TK/TMK have been demonstrated by using purified recombinant proteins. Since it does not encode all genes needed for DNA replication, WSSV depends on the host for other replication proteins. It has therefore been proposed that WSSV, like some

Fig. 7 Transmission electron micrograph of WSSV-infected tissues from beneath the cephalothoracic exoskeletal cuticle. (a) The viral particles spread among the necrotic area. The complete viral particles are indicated with arrows and the long empty tubules with an arrowhead. (b) High magnification of virus particles with rod-shaped morphology. A viral particle with an empty nucleocapsid is indicated with an arrow. From Leu, J.H., Tsai, J.M., Lo, C.F., 2008. White spot syndrome virus. In: Mahy, B.W.J., van Regenmortel, M.H.V. (Eds.), *Encyclopedia of Virology*, third ed. pp. 450–459.

other DNA viruses like herpesviruses and SV40 promotes S-phase arrest to maximize the DNA replication machinery. Part of the mechanism for S-phase arrest could involve WSSV IE1 and WSSV056 which bind to an Rb homolog in shrimp. This binding could activate host E2F1 leading to S1 arrest, as demonstrated in *Drosophila* cells overexpressing these two proteins.

Viral morphogenesis begins with *de novo* formation of the viral envelope, seen at first as fibrillar fragments in the nucleoplasm. These fragments form into the membranous and/or vesicular precursors of the viral envelope. Virus assembly begins with the packaging of the 300 kb viral genome into nucleocapsids. This packaging is mediated by binding of VP15 a basic viral DNA binding protein forming nucleoprotein complex fibers. The development of nucleocapsids begins with the formation of long empty tubules (Fig. 7) with a diameter like that of empty nucleocapsids and a segmentation similar to that of nucleocapsids. They can exist individually or may be laterally aligned in groups of two or three to form a larger structure. The assembled tubules break into fragments of 12–14 rings to form empty naked capsids which are then surrounded by envelopes, leaving an opening at one end. The filamentous nucleoprotein complex enters the capsid through this open end, while simultaneously increasing the diameter of the virion. Finally, the open end of the nucleocapsid is closed, and the envelope narrows at the open end to form the polar tail of the mature virion, which has now obtained its characteristic olive-like shape.

Apoptosis

Apoptosis is a cell suicide program that enables multicellular organisms to direct and control cell numbers in tissues and to eliminate cells, including virus-infected cells that may be harmful to the survival of the organism. If apoptosis occurs during the early stage of infection, virus production is severely limited. It is because it inhibits the spread of progeny virus in the host that apoptosis is recognized as an antiviral defense. The classical signs of apoptosis can be identified in WSSV-infected shrimp, including nuclear disassembly, fragmentation of DNA into a ladder, and increased caspase3 activity. Furthermore, there is a positive correlation between the severity of WSSV infection and the number of apoptotic cells. Among the WSSV target tissues, the subcuticular and abdominal epithelia are the most seriously damaged, and these epithelial tissues exhibit the highest incidence of apoptotic cells. However, it is significant that cells displaying apoptotic characteristics do not contain virions, whereas those containing WSSV virions are not apoptotic. It is therefore reasonable to suppose that apoptosis is employed by shrimp as a protective response to prevent the spread of WSSV. Viruses have evolved to inhibit apoptosis early in infection, allowing virus to replicate and to induce it later in infection to enhance virus release from infected cells, and WSSV is no exception. For example, WSSV anti-apoptosis protein 1 (AAP1 or WSSV449) binds to PmCaspase (in *P. monodon* animals). The resultant cleavage (at one site) of AAP1 by the caspase results in its inhibition. In another system pmCaspase is bound by WSSV134 and WSSV322

preventing caspase cleavage activity. Viral proteins, such as VP38 and VP41B can also influence apoptosis by binding the promoter of *PjCaspase* (in *P. japonicum*) to either repress expression (VP38) or activate it later in infection (VP41B). Another way WSSV induces apoptosis is through WSSV ICP11 which disrupts the binding of histones to DNA and disrupting nucleosome assembly, leading to apoptosis. Another viral protein, WSSV208, binds a mitochondrial protein COX5a, another protein which induces apoptosis by upregulating the transcription of apoptosis-related genes.

Hemocyte Responses to WSSV Infection

In crustaceans, the hemocytes (blood cells) mediate many defense-related activities that are essential for nonspecific immunity, including phagocytosis, melanization, encapsulation, cytotoxicity, and clotting. They also produce a vast array of antimicrobial proteins, such as agglutinins, antimicrobial peptides, and lysozymes. WSSV infection decreases the total hemocyte count (THC) in shrimp but not in crayfish. The reduced THC in shrimp is probably due to lysis by the virus of infected hemocytes as well as due to virus-induced apoptosis in both circulating hemocytes and hematopoietic tissue. In addition, circulating hemocytes migrate to tissues that have a high number of virus-infected cells, although this is probably a general defensive response rather than a specific antiviral response. WSSV infection also induces apoptosis in crayfish hemocytes but the percentage of apoptotic hemocytes is much lower in crayfish (1.5%) than in shrimp (20%).

WSSV infection differentially affects the three morphologically and functionally distinct crustacean hemocyte types, the semigranular cells (SGCs), granular cells (GCs), and hyaline cells (HCs). In shrimp and crayfish, both SGCs and GCs can be infected with WSSV but SGCs are the preferential target. This suggests that SGCs are more susceptible to WSSV and that the virus replicates more rapidly in SGCs than in GCs. However, the melanization activity of GCs in WSSV-infected crayfish is reduced. The HC type of hemocyte is refractory to WSSV infection in shrimp but their role in antiviral defense is still not clear. On the other hand, GCs and SGCs each play a major defensive role and WSSV infection of these cell types is likely to weaken shrimp defenses and reduce shrimp health. Since hemocytes are also necessary for clotting, the low THC also accounts for the phenomenon that hemolymph withdrawn from WSSV-infected shrimp and crayfish always has a delayed (or sometimes completely absent) clotting reaction.

Epidemiology

White spot disease is a highly contagious viral disease of penaeid shrimp. Its onset is rapid, and high levels of mortality can result within just a few days. Following the first outbreaks of WSD in Fujian Province, China in 1992 and Taiwan in 1993, this viral disease spread quickly to other shrimp-farming areas, including Japan, Thailand and Korea (1993), the United States (1995), other regions including Vietnam, Malaysia and Indonesia of Southeast Asia (1996), India (1998), Central and South America (1999), and France and Iran (2002). In 2008 it was detected in Mexico, then between 2010 and 2012 in Madagascar, Mozambique and Saudi Arabia and, more recently since 2016 it affected Australia. Essentially, WSD is considered endemic in almost all shrimp-producing countries particularly in Asia and the Americas, causing serious economic damage to the shrimp culture industry.

WSSV is highly virulent and can cause a cumulative mortality of up to 100% within 3–10 days of the first signs of disease at an annual loss of about one billion dollars. WSSV can be transmitted horizontally, either *per os* when the shrimp feed on diseased individuals, contaminated food or infected carcasses, or else through exposure to virus particles in the water, in which case the route of infection is primarily through the gills or other body surfaces. The virus is also transmitted vertically from brooder to offspring. However, transmission is not transovarial because the virus appears to attack only young developing oocytes, which die before reaching maturation. It is therefore more likely that vertical transmission is caused by contamination of the egg mass. Penaeid shrimp are highly susceptible to WSSV. Although there is evidence of resistance during the larval and early (younger than PL6) post-larval stages, WSSV can cause disease in shrimp at any growth stage.

WSSV has a remarkably broad host range. Almost every species of penaeid shrimp is susceptible to WSSV infection. Moreover, the virus can infect other marine, brackish, and freshwater crustaceans, including crayfish, crabs, and spiny lobsters. However, in contrast to penaeid shrimp, infection is often not lethal in these species, and consequently they may serve as reservoirs and carriers of the virus. Furthermore, at least one insect, the shore fly (a member of the family *Ephyridae*), as well as copepods collected from WSSV-affected farms, have been diagnosed as WSSV-positive by PCR, suggesting that they are also possible reservoir hosts.

In epidemiological studies of WSSV, variations in the number of the 54 bp tandem repeats located between the *rr1* and *rr2* genes have been used as a strain-specific, genetic marker. The number of repeats varies greatly when infected shrimps are collected from different ponds or from the same ponds at different times, but in almost every outbreak of WSD, shrimps from the same pond usually have the same number of repeats. This suggests that in each pond, a single WSSV isolate is the causative agent.

Clinical Features and Pathology

The most commonly observed clinical sign of WSD in shrimp is white spots in the exoskeleton and epidermis. These may range in size from minute spots to disks several millimeters in diameter which may coalesce into larger plates. The spots may result from

abnormal deposits of calcium salts by the cuticular epidermis or result from disruption to the transfer of exudates from the epithelial cells to the cuticle. Infected animals are lethargic, reduce their food consumption, and display a reddish to pink body discoloration due to expansion of cuticular chromatophores. Moribund shrimp exhibit systemic destruction of target tissues with many infected cells showing homogeneous hypertrophied nuclei. At advanced stages of infection, numerous virus particles are released into the hemolymph from the lesions, causing a general viremia.

It should be noted that although the white spots are a typical and characteristic clinical sign of WSD, white spots on the carapace of shrimp can also be caused by other environmental stress factors, such as high alkalinity or a bacterial shell disease. Conversely, moribund shrimp with WSD may have few, if any, white spots.

To date, no species of penaeid shrimp is known to show significant resistance to WSD.

Protection of Shrimp Against WSSV Infection Using Vaccination and RNAi Strategies

Considering the economic impact of WSSV on the shrimp and crab industries, it is not surprising that a lot of research has gone into trying to mitigate the disease. These include efforts to enhance the immune system, use of vaccines and RNAi and discovery or development of antivirals. When *P. japonicus* shrimps survive either natural or experimental WSSV infections, they sometimes show resistance to subsequent challenge with WSSV. This 'quasi-immune response' suggests that shrimps may have an innate immune system that includes specific memory. Several vaccines including sub-unit, whole virus-inactivated, DNA and RNA based vaccines using different modes and times of vaccination have been developed with varying degrees of success. In earlier studies inactivated bacteria expressing VP28 (but not VP19) provided survival up to about 71%, but the protection is relatively short lived to less than 21 days postvaccination. For example, oral administration by continuous feeding of *Bacillus subtilis* spores expressing VP28 antigen even at low concentrations, provided about 70% protection. Through a metanalysis, Shu-Ying Feng and colleagues demonstrated that RNA-based vaccine showed the best protection and that of the subunit vaccines, VP26 had the best protective effects. Among different routes of administration, oral, immersion and injection, oral administration was the best. RNAi against different WSSV genes has also been tested as a treatment method. For example, injection of *M. japonicus* with vp28-siRNAs encapsulated with β -1,3-D-glucan inhibited WSSV replication. In a later study, injection of dsRNA targeting the VP28 mRNA provided nearly complete protection for WSSV infection. While RNAi seems to be effective, injection would be too labor intensive as a treatment regimen.

Many natural products have been shown to be particularly effective in limiting virus infection. Alginate from the seaweed *Sargassum siliquosum*, provided about 56% survival rates. Epigallocatechin-3-gallate (EGCG) extracted from green tea reduced WSSV production in the mud crab *Scylla paramamosain* and Kuruma shrimp (*Marsupeneaus japonicus*). An additional effect of EGCG treatment was that it correlated with increased expression of immune-related genes such as those for proPO, Rho, Rab7, p53, TNF- α , MAPK and NOS, improving innate immunity. Hesperetin, a flavanone compound from lemons and oranges, has multiple anti-inflammatory, anti-cancer and anti-viral (e.g., against herpes simplex virus type 1, poliovirus, respiratory syncytial virus) characteristics. Treatment of crayfish with hesperetin reduced mortality in WSSV infections and increased expression of innate immunity-related genes such as NF- κ B and C-type lectin. Other extracts that have shown promise are ones derived from *Cynodon dactylon* (Bermuda grass), *Ceriops tagal* (Indian mangrove), *Momordica charantia* (bitter melon) and *Agathi grandiflora* (vegetable hummingbird). Some host proteins including LvGP (*Litopenaeus vannamei*, Glycogen phosphorylase), PmGILT enzyme (*Penaeus monodon*, Gamma-interferon-inducible lysosomal thiol reductase) and LvSrc64B (*L. vannamei*, Src family kinases) showed antiviral activity against WSSV.

Nomenclature

AHPND Acute hepatopancreas necrosis disease
BBV Black beetle virus
BFNNV Barfin flounder nervous necrosis virus
BoV Boolarra virus
CMD Covert mortality disease
CMNV Covert mortality nodavirus
CPE Cytopathic effects
cryoEM Electron cryomicroscopy
EMS Early mortality syndrome
FHV Flock House virus
MrNV *Macrobrachium rosenbergii* nodavirus
NNV Nervous necrosis virus
NoV Nodamura virus
PaV Pariacoto virus

PL Post-larvae
qPCR Quantitative PCR
qRT-PCR Quantitative reverse-transcription PCR
RdRp RNA-dependent RNA polymerase
RGNNV Redspotted grouper NNV
RT-LAMP Reverse-transcription loop-mediated rapid isothermal amplification
RT-PCR Reverse-transcription PCR
SJNNV Striped Jack NNV
TPNNV Tiger puffer NNV
VCMD Viral covert mortality disease
VER Viral encephalopathy and retinopathy
VLP Virus-like particle
VNN Viral nervous necrosis
WTD White tail disease

Classification (Compact): Family *Nodaviridae*, genera *Alphanodavirus* and *Betanodavirus*

The family *Nodaviridae* in the order *Nodamuvirales* is divided into two canonical genera: *Alphanodavirus* with five species including *Nodamura virus* as the type species and *Betanodavirus* with four species including *Striped jack nervous necrosis virus* as the type species.

Alphanodaviruses are primarily virus pathogens of insects. They include Nodamura virus (NoV, a member of the type species), Flock House virus (FHV), black beetle virus (BBV), Boolarra virus (BoV), and Pariacoto virus (PaV).

Viruses of the *Betanodavirus* genus are the causative agents of viral nervous necrosis (VNN) in infected fish. Consequently, the nomenclature used for most betanodaviruses is the name of the host species followed by “nervous necrosis virus” (NNV). The viruses are classified into four genotypes based on genome homology: Redspotted Grouper NNV (RGNNV), Barfin Flounder NNV (BFNNV), Striped Jack NNV (SJNNV), and Tiger Puffer NNV (TPNNV). RGNNV and SJNNV are serologically distinct from one another and from the cold-water betanodaviruses BFNNV and TPNNV. Corresponding serogroups A (SJNNV), B (RGNNV), and C (BFNNV/TPNNV) have been proposed to reflect these serological relationships. The placement of reassortant viruses that contain RNA1 from RGNNV and RNA2 from SJNNV (RGNNV/SJNNV) in serogroup A and those that RNA1 from SJNNV and RNA2 from RGNNV (SJNNV/RGNNV) in serogroup C indicates that the capsid protein encoded by RNA2 is a major antigenic determinant.

The discovery of nodaviruses that infect shrimp and their low sequence homology with either Alphanodaviruses or Betanodaviruses has led to the proposal of a third genus, *Gammanodavirus*, to include *Macrobrachium rosenbergii* nodavirus (MrNV) and *Penaeus vannamei* nodavirus (PvNV). These viruses have been isolated from the giant river prawn (*M. rosenbergii*) and the white leg or Pacific white shrimp (*P. vannamei*), respectively, and share approximately 80% similarity at the amino acid level. Two other shrimp nodaviruses, covert mortality nodavirus (CMNV) and *Farfantepenaeus duorarum* nodavirus (FdNV), have also been proposed for inclusion in this group. While *Macrobrachium rosenbergii* nodavirus (MrNV) remains in the family *Nodaviridae*, a satellite of MrNV called extra small virus (XSV) that was originally classified as a nodavirus has been reclassified as the sole member of a newly established virus family, the *Sarothroviridae*. The *Sarothroviridae* were named for the small arthropod hosts (shrimp, some insects) they infect.

Provisional Nodaviruses

Additional viruses have been proposed as potential members of the family *Nodaviridae*, as summarized in [Table 1](#), although none have yet been officially classified as nodaviruses by the ICTV.

Proposed Six Clade Taxonomic Structure

While previous nodavirus phylogenies have relied on the relationship between the capsid proteins, yielding the current 2 genera (*Alphanodavirus* and *Betanodavirus*) and the proposed *Gammanodavirus* genus, more recent alignments using the RdRp protein sequence have suggested a broader taxonomic structure, particularly when considered together with a number of newly discovered viruses that share significant sequence homology with one or more recognized nodaviruses. Clade 1 includes all of the recognized

Table 1 Provisional nodaviruses

<i>Virus name</i>	<i>Abbreviation</i>	<i>Source of isolate</i>
Bat guano-associated virus	BGNV	Bat species, including the Brazilian free-tailed bat (<i>Tadarida brasiliensis</i>), cave myotis (<i>Myotis velifer</i>), evening bat (<i>Nycticeus humeralis</i>), and/or the tricolored bat (<i>Perimyotis subflavus</i>)
Culannivirus	CuNV	<i>Culex annulirostris</i> mosquitoes
Hypsignathus nodavirus	HSNV	Fruit bats (<i>Hypsignathus monstrosus</i>)
Le Blanc nodavirus	LBNV	Nematodes (<i>Caenorhabditis briggsae</i>)
Lutzomyia Plaiui nodavirus	LPNV	Phlebotomine sand flies (<i>Lutzomyia longipalpis</i>)
Mosinivirus	MoNV	<i>Culex nebulosus</i> and <i>Culex</i> sp. mosquitoes
Orsay virus	ONV	Nematodes (<i>Caenorhabditis elegans</i>)
Santeuil nodavirus	SNV	Nematodes (<i>Caenorhabditis briggsae</i>)
Wuhan nodavirus	WhNV	Small cabbage white butterfly larvae (<i>Pieris rapae</i>)

alphanodaviruses except PaV; Clade 2 includes the betanodaviruses and several newly discovered noda-like viruses isolated from different arthropod hosts. Clade 3 includes PaV, MrNV, and CulV and is considerably more diverse than the other proposed clades, particularly MrNV. Clade 4 includes several newly sequenced isolates; Clade 5 includes one isolate from *Helicoverpa zea* and several newly sequenced isolates from diverse insect hosts, and Clade 6 includes SNV, ONV, and LBNV, all isolated from nematodes.

Virion Structure

Nodavirus particles are comprised of a protein shell co-encapsidating one copy each of the two genomic RNA molecules. The three dimensional structures of several members of the *Nodaviridae* have been solved by cryo electron microscopy (cryoEM) and/or x-ray crystallography (BBV, FHV, NoV, PaV, MrNV). The unique features of each are characterized below.

The structures of alphanodaviruses BBV, FHV, and NoV are all closely similar. The viral capsid consists of 180 coat protein subunits arranged with icosahedral symmetry on a T=3 quasi-equivalent lattice. Although the primary structures of the coat protein subunits are identical, they occupy three quasi-identical locations (A, B, and C) in the icosahedral asymmetric unit. The A subunits are related by 5-fold symmetry, while the B and C subunits are related by three-fold symmetry. However, only ~15% of the viral RNA is visible in these structures. Strikingly, cryoEM image reconstruction and the crystal structure of PaV revealed the presence of a dodecahedral cage comprised of duplex RNA, representing approximately 35% of the viral single-stranded RNA genome. The highly basic N-terminal regions of the capsid protein that form pentamers (the A subunits) make contacts with the RNA cage structure.

The capsid structure of recombinant virus-like particles (VLPs) of a malabaricus grouper nervous necrosis virus (MGNNV) (*Epinephelus malabaricus*) nodavirus VLP differs from that of the insect nodaviruses. Its protein fold more closely resembled those of Norwalk virus and tomato bushy stunt virus than that of the alphanodaviruses.

The structural arrangement of the *Machrobrachium rosenbergii* nodavirus (MrNV) capsid also differs from those reported for the alphanodaviruses. While MrNV shares an 8-stranded antiparallel beta barrel capsid protein structure with the other nodaviruses, it lacks the canonical nodavirus trimeric “spike” at the isocahedral vertex at the 5-fold axis and the MrNV capsid protein forms a dimeric spike in the equivalent position. Many similarities were seen between the MrNV capsid and that of tombusviruses, including the coordination of calcium ions (3 pairs in each asymmetric unit) and an overall similar fold to that of the tombusvirus spike protein.

Genome

As shown schematically in [Fig. 1](#), the nodavirus genome is divided into two segments of positive strand ssRNA with non-methylated 5' cap structures and lacking poly(A) tails. The larger segment, RNA1, encodes the viral RNA-dependent RNA polymerase (RdRp), while RNA2 encodes the capsid protein precursor (see below). During replication of RNA1, a small subgenomic RNA (RNA3) is synthesized and subsequently replicated. RNA3 encodes proteins B1 and B2, whose functions are described below. For FHV, replication of RNA2 suppresses RNA3 synthesis, yet viral mutants that do not make RNA3 fail to replicate RNA2. If RNA3 is provided *in trans* from an exogenous source, RNA2 replication is restored. This interdependence may assist in coordinating replication of the two segments, which must be co-encapsidated during virus assembly.

Proteins

RNA-Dependent RNA Polymerase (RdRp)

Protein A (110 kDa) is the sole catalytic subunit of the RNA-dependent RNA polymerase that replicates the genomic RNA. It also possesses an RNA capping (guanylyl transferase) activity. This protein is membrane-associated (via either a transmembrane region or a membrane-association region that may involve only a single leaflet of the membrane, depending on the virus) and establishes

Fig. 1 Schematic of nodavirus genome organization. Genomic RNA1 and RNA2 as well as subgenomic RNA 3 are shown schematically. All three are capped (unmethylated cap 0 structure) but not polyadenylated. RNA1 encodes the viral RdRp, RNA3 encodes small proteins B1 and B2 in overlapping reading frames, and RNA2 encodes the capsid protein (CP; betanodaviruses) or the capsid protein precursor alpha, which is autocatalytically cleaved into mature capsid proteins beta and gamma (alphanodaviruses). RNAs 1 and 2 are copackaged into the same virion, while subgenomic RNA3 is not packaged.

viral replication complexes in association with the cellular outer mitochondrial membrane. For betanodaviruses, the N-terminus of the RdRp is associated with their ability to replicate at colder temperatures (thermotolerance).

Capsid Proteins

The nodavirus capsid consists of 180 copies of the viral capsid protein (CP). For alphanodaviruses, the capsid protein (CP) is initially translated as a precursor, protein alpha, which undergoes an auto-catalytic maturation cleavage after assembly to yield the mature capsid proteins beta and gamma found in the virion. For betanodaviruses, this cleavage is not observed but the capsid protein undergoes an essential conformational change to produce mature virions. The betanodavirus CP contains an N-terminal signal for localization to the nucleolus, where it plays a role in cell cycle arrest. Its accumulation later in infection induces apoptosis via a caspase-dependent mechanism. The C-terminus of the CP may play a role in host specificity.

Proteins B1 and B2

Two small proteins, B1 and B2, are translated from RNA3. B1 is in the same reading frame as the RdRp and is identical to its C-terminus, although not all betanodaviruses are predicted to encode B1. B2 is translated in an overlapping reading frame. In alphanodaviruses, the function of B1 is unknown. For betanodaviruses, B1 serves as an anti-necrotic “death factor” that results in loss of mitochondrial membrane potential. For RGNNV, the subcellular localization of B1 transitions from the cytoplasm to the nucleus late in infection, resulting in cell cycle arrest. B2 suppresses RNA interference (RNAi) by binding to and sequestering double-stranded RNA replication intermediates. Betanodavirus B2 serves as a necrotic “death factor” that upregulates proapoptotic protein Bax and induces loss of mitochondrial membrane potential but not release of mitochondrial cytochrome C. However, in alphanodaviruses, B2 is not associated with apoptosis and while FHV infection does induce caspase-dependent apoptosis in infected cells, NoV does not.

Physical Properties

Nodaviruses are non-enveloped, small (29–32 nm diameter) icosahedral viruses that contain bipartite positive-strand ssRNA genomes. Alphanodavirus particles are resistant to chloroform, diethyl ether, 1 M urea, 20 mM EDTA and 1% sodium deoxycholate and all except Boolarra virus (BoV) are stable in 1% SDS. Immature provirions are sensitive to these denaturants and to freezing. FHV is stable at 40°C for 10 min, but loses infectivity when heated at 58°C. FHV, BoV, and NoV are stable over a wide range of pH values (pH 3–10). NoV is unstable in the presence of chloride ions and BBV and LNV_C are unstable when stored in cesium chloride (CsCl), while FHV is stable in CsCl.

Betanodaviruses are resistant to aquatic environments and can survive at low temperatures in seawater. Infectivity of viruses contained in seawater decreases at temperatures above 25°C while that in drying conditions lose infectivity at 21°C. Betanodavirus particles are inactivated by hydrogen peroxide, benzalkonium chloride, iodine, and sodium hypochlorite but resistant to formalin. While MrNV particles are stable to storage in a cell lysate or tissue sample at –20°C and –70°C, their infectivity is lost upon experimental heat treatment (65°C for two hours). The chemical stability of MrNV particles is unknown.

Life Cycle

The ecological life cycle of Alphavodaviruses is unknown. Nodamura virus was isolated from mosquitoes and found to cause lethal infections in suckling mice when introduced experimentally via the intracranial (IC) route. NoV can also be transmitted from an infected mouse to a naïve one by mosquitoes and cause lethal infections in both vertebrates (suckling mice and suckling hamsters) and invertebrates (mosquitoes, honeybees, larvae of the greater wax moth, and fruit flies). The remaining alphavodaviruses have been isolated from only insects, including FHV, BBV, BoV, but little is known about their transmission in the wild. However, the infectious cycle of the viruses is well understood due to their ready replication in a variety of cultured cells from both vertebrates and invertebrates, and in transformed yeast cells. Betanodaviruses infect primarily larvae and juvenile fish. They can be transmitted to juvenile farmed fish populations from wild reservoir species or through importation of infected juveniles from other farms. The literature suggests that betanodaviruses most likely infect the intestinal epithelium and peripheral nervous system, are rapidly transmitted to the central nervous system, and result in either death or persistence in survivors. The virus is thought to spread to the environment by decomposition of dead fish.

Little is known about the natural transmission cycle of *Macrobrachium rosenbergii* nodavirus (MrNV). Both horizontal and vertical (*trans*-ovum) transmission by the water-borne route have been observed. Outbreaks of WTD disease may be induced or enhanced by rapid environmental changes such as those in pH, salinity, and temperature. Similarly, survival of shrimp with symptoms of covert mortality disease or viral covert mortality disease decreases sharply with water temperatures above 28°C.

Epidemiology

Over 50 species of fish are susceptible to betanodavirus infections. In particular the marine fish species striped jack (*Pseudocaranx dentex*), European sea bass (*Dicentrarchus labrax*), groupers (*Epinephelus* species), and flatfishes. These diseases primarily affect farmed fish, which are particularly vulnerable to infectious diseases due to the high densities at which the fish are raised. In general, the earlier the age at which betanodavirus disease signs and symptoms occur, the greater the mortality. In larval striped jack, the disease can occur within two days of hatching with the peak mortality observed at 10 days post-hatching, resulting in almost complete loss of the larvae. In European sea bass, mortality is most frequently seen 30-days post-hatching but may occur in adults as well as larvae and juveniles. The disease has been reported from countries in the Mediterranean region (France, Greece, Israel, Italy, Malta, Portugal, Spain, and Tunisia), in the Atlantic region (Norway and the United Kingdom), in North America (Canada and the United States), and in Asia (Chinese Taipei, India, Indonesia, Iran, Japan, Korea, Malaysia, the Philippines, the Peoples Republic of China, Thailand, and Vietnam). In Japan, a representative sample of 30 species in two geographically distinct regions confirmed that most farmed and wild fish tested positive for VNN.

White tail disease (WTD) in the giant river prawn *Macrobrachium rosenbergii* is caused by infection with MrNV. The disease has been reported in Australia, Chinese Taipei, the French West Indies (the islands of Guadeloupe and Martinique), India, Malaysia, the Peoples Republic of China, and Thailand. PCR-positive results but no active infection have been obtained with other crustacean species, including brine shrimp (*Artemia* sp.), red claw crayfish (*Cherax quadricarinatus*), Monsoon River prawn (*Macrobrachium malcolmsonii*), hairy river prawn (*M. rude*), Indian white prawn (*Penaeus indicus*), kuruma prawn (*Penaeus japonicus*), and the giant tiger prawn (*Penaeus monodon*). In the latter three marine shrimp species, infection could not be initiated by the oral route, but intramuscular inoculation resulted in accumulation of particles in abdominal muscle, gill, hemolymph, intestine, and stomach that were infectious when inoculated into *M. rosenbergii* postlarvae (PL). Similar results have also been described in several insect species, including dragonfly (*Aeshna* sp.), giant water bug (*Belostoma* sp.), beetle (*Cybister* sp.), and backswimmer (*Notonecta* sp.). For MrNV, only larvae, PL, and early juveniles are susceptible, while adults are resistant. No mortality has been reported in subadult or adult prawns naturally or experimentally infected with MrNV.

Covert mortality disease (CMD) or viral covert mortality disease (VCMD) is an emerging shrimp disease caused by covert mortality nodavirus (CMNV). The name CMD derives from moribund shrimp hiding in deep water rather than swimming to the surface or in shallow water. Initially identified in *Litopenaeus vannamei* (formerly *Penaeus vannamei*; common name white leg shrimp or Pacific white shrimp), specimens of *Marsupenaeus japonicus* (Japanese tiger prawn or Kuruma prawn) and *Fenneropenaeus chinensis* (Chinese white shrimp or fleshy prawn) isolated from diseased ponds exhibit similar symptoms. An outbreak of VCMD in 2012–2014 resulted in heavy loss of farmed *M. japonicus* and *F. chinensis* in the municipalities of Tianjin and Hebei and Shandong Provinces in China. A recent three-year epidemiological survey determined the prevalence of CMNV in samples of *L. vannamei*, *F. chinensis*, *Marsupenaeus japonicus*, *Macrobrachium rosenbergii*, and *Penaeus monodon* collected from 145 sampling site shrimp farms in ten coastal provinces in China. The prevalence was highest in Guangdong and Hainan Provinces (approximately 50%), 25%–30% in Hebei, Shandong, Jiangsu, Zhejiang, and Fujian Provinces, 17% in Guangxi Province, and approximately 10% in Liaoning and Tianjin Provinces. Other studies have reported on isolation of CMNV-positive shrimp from Ecuador, Thailand, and Vietnam, suggesting a wide distribution.

Clinical Features

VNN

Betanodaviruses are the causative agents of viral nervous necrosis (VNN), also known as viral encephalopathy and retinopathy (VER). Most common clinical signs included aberrant swimming (horizontal swimming, looping, darting, spiral swimming, or whirling), loss of

appetite, hyperinflation of the swim bladder, and lightening or darkening of the coloration. Nerve cells in the cerebellum and olfactory lobe exhibit vacuolization and infected cells have been detected in the spinal cord, medulla oblongata, thalamus, and preoptic area. However, the clinical signs depend on the fish species, developmental stage, water temperature, and the phase of the disease. For example, while juvenile fish may be severely affected, adults are often less so. Further information on VNN may be obtained from the OIE Reference Laboratory for Viral encephalopathy and retinopathy and the excellent review by Bandín and Souto (see Further Reading).

WTD

Clinical signs include lethargy and whitening or opaqueness of the abdominal muscles. PL become opaque and develop a milky, white appearance. This whitish discoloration appears first in the second or third abdominal segment and diffuses gradually in both anterior and posterior directions. In severe cases, the last pair of abdominal legs (uropods) and the tail fan (comprised of uropods and telson) may degenerate. Mortality generally peaks 5–6 days after onset of symptoms and very few PL survive beyond 15 days. PL that do survive can reach normal market size. Due to the possibility of persistent infection, adults can serve as carriers.

VCMD

Clinical signs include hepatopancreatic atrophy with color fading and necrosis, empty stomach and guts, soft shell, slow growth, and often abdominal muscle whitening and necrosis. Daily reports of mortality within a population begin within one month and increase during a 60–80 day period post-stocking, with a total mortality of approximately 80%. Although these symptoms are somewhat similar to those caused by early mortality syndrome (EMS)/acute hepatopancreas necrosis disease (AHPND), caused by a bacterial pathogen, CMD and EMD/AHPND are distinct from one another. As a result, covert mortality disease (CMD) was renamed viral covert mortality disease (VCMD) to reduce confusion between the diseases.

Pathogenesis

Betanodaviruses replicate in brain, spinal cord, and retina of a number of fish species, resulting in vacuolization of the brain and retina together with cellular necrosis and neural degeneration. Often large vacuolar lesions are seen in larvae and juveniles while adults exhibit mild or absent symptoms. Infected striped jack larvae also exhibit hyperplasia and degeneration of epithelial cells of the skin, oral cavity, and gills. The tissue distribution appears to differ between larvae/juvenile fish and adults, with greater vacuolization in the spinal cord and medulla oblongata seen in the earlier developmental stages.

In MrNV-infected PL and early juveniles, striated muscles of the tail, abdomen, and cephalothorax are affected. Histological examination reveals acute Zenker's necrosis of striated muscles, with severe hyaline degeneration, muscular lysis, and necrosis. Abnormal open spaces, moderate edema, and basophilic cytoplasmic inclusions are observed among infected muscle cells. Transmission electron microscopy reveals a disorganized cytoplasm and the presence of not only MrNV but also a satellite virus (extra small virus, XSV). XSV was initially classified as a member of the *Nodaviridae* but was moved recently into its own family, the *Sarothroviridae*.

Covert mortality nodavirus (CMNV) causes multifocal myonecrosis in striated muscle, accumulation of vacuoles in the cytoplasm of hepatopancreocytes, eosinophilic inclusions in the tubular epithelium of the hepatopancreas, and spheroids in the lymphoid organ with inclusions and nuclear condensation of the chromatin.

Immune Responses to Nodavirus Infection

Innate Immune Responses

Host immune systems are equipped with a variety of tools in their antiviral arsenal. Innate immune responses to viral infection can typically be classified within seven primary categories: (1) activation of Pattern Recognition Receptors (PRR) capable of binding Pathogen-Associated Molecular Patterns (PAMPs); (2) production of siRNAs, miRNAs, and piwiRNAs that target viral RNA for degradation and inhibit replication; (3) activation of signaling pathways such as Toll, NF- κ B, and Imd; (4) activation of Jak-STAT pathways that act in a fashion similar to interferon pathways in mammals which control transcription and antiviral replication; (5) triggering of autophagy which can recycle damaged organelles and engage in signaling through the PI3K-Akt and TOR pathways; (6) production of interferon-like molecules and inflammatory cytokines; and (7) cytotoxic T cell responses that activate granzymes and perforins.

Activation of the PRR through the binding of viral-associated nucleic acids to Toll-like receptors lead to the activation of a number of signaling molecules including TRIF, MyD88, NF- κ B, Interferon Regulatory Factors (IRF), and MAPK that stimulate the production of cytokines, chemokines, and interferon-like proteins to suppress viral replication. Anti-microbial Toll-responses from PRRs led to activation of serine proteases and signal transduction, resulting in nuclear translocation and regulation of effector genes. Both Toll and Imd pathways are linked to NF- κ B signaling in innate immune responses by activation of cellular transcription. Upregulation and expression of genes in both pathways has been observed in nodavirus-infected species.

Silencing of viral RNA occurs most commonly through the production of complementary silencing RNAs (siRNAs) and microRNAs (miRNAs) that prevent transcription and regulate gene expression. *P*-element Induced WImpy (PIWI) or piRNAs are a type of RNA distinct from miRNAs whose role is to exert epigenetic control of germline genomic elements in vertebrates. MiRNAs

and piRNAs have been identified in invertebrates, however, their role in transcriptional regulation particularly in insects is not well-understood. Evaluation of their role has suggested that production of piRNA precedes that of siRNA then wanes. Blockage of piRNA leads to increased viral replication and the accumulation of viral particles, suggesting a regulatory role. In response to these regulatory pathways, nodaviruses have developed mechanisms to suppress the function of both host siRNA and miRNA activity by producing proteins and subgenomic RNAs including B2 and dicer that bind and promote cleavage of dsRNA. Jak-STAT pathways can respond to viral activation through multiple mechanisms including dephosphorylation, nuclear export, or negative feedback. The activation of this pathway results in changes in the transcription profile of infected organisms. This upregulation is not due to dsRNA alone, but requires active viral replication and production. Jak-STAT pathway mRNA expression is increased in nodavirus-infected hosts, supporting an anti-viral role for this pathway. Importantly, infection of hosts with different nodaviruses led to differential expression of Jak-STAT pathway members, indicating that other pathways may be involved. Furthermore, STAT can also repress gene activity by forming complexes with other transcription factors and chromatin-modifying proteins that regulate NF- κ B immune responses. Toll ligands, cecropins, and defensins can also be downregulated, supporting the notion that JAK-STAT activation can lead to inhibition of Toll-regulated genes, thus regulating anti-viral responses.

Autophagy is another mechanism that infected hosts use to regulate viral transcription and translation. In this process, *de novo* synthesized membranes encompass large cytoplasmic components including damaged organelles or protein aggregates containing viral components that join with lysosomes to form autolysosomes which degrade and recycle digested materials. Positive and negative regulation of autophagy occurs primarily through the phosphoinositol 3-kinase-related-kinase (PI3K-Akt) and Target of Rapamycin (TOR) pathways, respectively. Knockdown of autophagy-related genes results in higher viral production and prevents the formation of autolysosomes, supporting its role in viral suppression. Phosphorylation of PI3K-Akt was shown to downregulate TOR activation and increase autophagy which subsequently leads to decreased viral replication.

Interferons and other inflammatory cytokines are a crucial aspect of the host antiviral response and help by inhibiting viral replication and promoting a pro-inflammatory phenotype. Viral pathogens such as NoV can promote activation of Interferon Specific Response Elements (ISRE) through two common pathways. Pattern Recognition Pathways (PRRs) that include RIG-I (retinoic acid-inducible gene I) and MDA5 (melanoma differentiation-associated protein 5) can sense double-stranded RNA in the cytoplasm. Once this occurs, these proteins can trigger the activation of MAVS (mitochondrial antiviral signaling protein) which, in turn, subsequently activates a complex composed of Tank Binding Kinase 1 (TBK1) and I κ B kinase- ϵ (IKK ϵ). Stimulation of the TBK1/IKK ϵ complex drives the phosphorylation of interferon regulatory factors 3 and 7 (IRF3 and IRF7), which translocate to the nucleus and bind to the ISRE promoters that upregulate transcription and translation of interferon- β and other Interferon-stimulated genes (ISGs). Viral PAMPs are recognized through Toll-like receptors 3, 7 and 8 (TLR3, 7, and 8), which specifically recognize viral dsRNA and ssRNA in the endosome and signal through TRIF (TIR-domain-containing adapter-inducing interferon- β) and MyD88 (Myeloid differentiation primary response 88). Activation of these factors triggers phosphorylation of IRF5 and IRF7 and downstream upregulation of ISGs and Type I Interferon production. TRIF can also activate the TBK1/IKK ϵ complex, thus amplifying the antiviral response.

Multiple mechanisms used by viruses to inactivate this pathway have been identified including the prevention of dephosphorylation keeping signaling proteins like MDA5 in an inactive state, blocking the ATPase activity or preventing ubiquitination of RIG-I, modulation of miRNAs that block MDA or RIG-I upregulation, or direct cleavage or degradation of MDA5, MAVS and RIG-I. Nodaviral RNA replication complexes promote progressive clustering and aggregation of mitochondria within the cell culminating in malformation of muscle fibers, tissue damage and paralysis. Because nodavirus RdRp's localize to the outer mitochondrial membrane, it is critical that these viruses prevent or modulate host antiviral activity. Because the NoV RdRp associates with MAVS (Johnson, personal communication), mechanisms using such strategies as direct cleavage and degradation of mitochondrial membrane-associated proteins like MAVS and likely STING (Stimulator of interferon genes) or their sequestration in virally-induced autophagosomes (Johnson, unpublished) are likely to be required to control the innate host response.

Adaptive Immune Responses in Nodavirus Infection

T cells are a crucial component of antiviral immunity and can determine whether a viral infection will be controlled and whether lasting immunity will be elicited. T cell responses have been characterized in only a limited number of studies in response to nodavirus infection. Data suggest that there is a specific role for cytotoxic T lymphocytes (CTL) in the modulation of nodavirus infection that is dependent upon MHC Class I and antigen-presenting cells. CTL responses have been characterized by the upregulation of cell markers, inflammatory cytokines and mediators of genes associated with cell lysis including granzyme, perforin and others. Importantly, this activity was limited in some species and allowed virally infected cells to evade killing. Other studies have confirmed observation of increased levels of T cell markers and Type II interferon following immunization with nodavirus, further suggesting that CD4⁺ T cells may also play a critical role in the reduction of viral loads.

Diagnosis

VNN

Diagnosis of a suspect case of VNN (VER) depends on at least one of the following criteria: abnormal swimming behavior in susceptible species; typical histopathological lesions in a susceptible species; typical cytopathic effects (CPE) observed in cell cultures; detection of specific antibody reactivity; any positive result obtained by RT-PCR and subsequent genomic sequencing,

quantitative PCR, or histopathology; transfer of live fish from an infected farm to another site; or the existence of epidemiological links between an infected farm and another farm. A confirmed case is one in which positive results are obtained from at least two of the following methods: a suspect case that has produced typical CPE in cell culture plus identification of the causative agent by a molecular test or an antibody-based test and a second diagnostic assay that might include isolation from cultured infected cells followed by immunostaining, reverse transcription PCR (RT-PCR), or quantitative RT-PCR (qRT-PCR). While serological diagnostic methods are not yet used as a screening method for assessing the presence of *Betanodavirus* species in fish populations, a recent study generated novel antibodies suitable for development as a serological test for diagnosis of VNN.

WTD

Diagnosis of a suspect case of WTD requires that at least one of these criteria are met: clinical signs or histopathology consistent with MrNV infection or a positive result by RT-PCR or qRT-PCR. A confirmed case fulfills two or more of the following: MrNV-positive histopathology, positive result in target tissues, RT-PCR followed by sequencing, or qRT-PCR. MrNV can be detected by *in situ* hybridization of histological specimens using a digoxigenin-labeled probe. Although no serological methods have been developed to date, both genome (qRT-PCR) and antibody-based (ELISA) tests are available for diagnostic use. The virus can be propagated in nodavirus-susceptible cultured cell lines including those of the mosquito *Aedes albopictus* line C6/36 and the fish *Channa* (Ophicephalus) *striatus* (striped snakehead) line SSN-1. No specific CPE is observed but viral replication can be detected by acridine orange staining, quantitative RT-PCR, and EM.

VCMD

Diagnosis of shrimp exhibiting suspected clinical signs of CMD has been accomplished using various nucleic acid amplification tests including RT-LAMP, nested RT-PCR, and qRT-PCR. The RT-LAMP and RT-PCR assays test RNA isolated from the cephalothorax of suspected CMNV-infected shrimp. Because the RT-LAMP assay uses a fluorescent dye for detection rather than gel electrophoresis or qRT-PCR, it is suitable for use as a rapid detection method in the field.

Treatment

No treatment is available for nodavirus infection.

Prevention

VNN

Virus contaminated water can be sterilized by UV treatment. Fertilized fish eggs may be washed in ozone-treated seawater to remove viral particles from their outer surfaces. Treatment of rearing water with chlorine or ozone appears effective in controlling the disease in larvae of striped jack, sevenband grouper, barfin flounder, and Atlantic halibut. Immunization with recombinant viral capsid protein or virus-like particles or with formalin-inactivated virus has proven effective in preventing VNN. An inactivated RGNNV preparation that protects sevenband grouper from RGNNV infection is commercially available in Japan. More recently, the production of antisera that are specific for the capsid proteins of SJNNV, RGNNV, TPNNV, and BFNNV suggested the possibility of developing antibody-based vaccines that might prove cross-protective against all four betanodavirus genotypes.

WTD

Prevention may be accomplished using standard procedures for control of crustacean viral diseases, including use of iodophors or formalin to disinfect eggs and larvae. Preventive measures include disinfection of tanks and water supplies and screening of brood stock and PL to maintain pathogen-free populations. The OIE Manual of Diagnostic Tests for Aquatic Animals recommends against mixed cultures of *M. rosenbergii* and the giant tiger prawn *Penaeus monodon* or rotation between the two species in the same tank to decrease the likelihood of spread. No vaccine is available for WTD.

VCMD

Preventative measures include deployment of a reverse transcription loop-mediated rapid isothermal amplification (RT-LAMP) detection kit for screening brood stock for CMNV prior to stocking of ponds and adoption of indoor culture methods. No vaccine is available for VCMD.

Glossary

Baculovirus Member of the *Baculoviridae* family of occluded viruses that are pathogenic to insects and other invertebrates. The salient features of the viruses are their rod-shaped nucleocapsids and large circular, double-stranded, supercoiled DNA genome.

Episome A non-integrated extrachromosomal closed circular DNA molecule that may be replicated in the nucleus with chromosomal DNA.

Latent infection Viral infection without cell lysis, the viral genome but not virus particle is detectable.

Nucleocapsid Protein shell that encloses the viral genetic material.

Nudivirus Viruses that are generally not packed in an occlusion body.

Occlusion body A viral-encoded protein lattice that packs and protects the viruses in the environment.

Persistent infection Viral infection without cell lysis, but with the appearance of virus particles.

Productive/lytic infection A form of viral infection in which large numbers of viruses are produced and that usually results in cell lysis.

Classification

History

Nudiviruses are a highly diverse group of rod-shaped, enveloped, and circular double-stranded DNA (dsDNA) viruses. These viruses infect a wide variety of arthropod hosts including insects and crustaceans (shrimp). The word “Nudi-” comes from the Latin “*nudus*”, meaning naked, as several of the initially described members of this viral group do not produce occlusion bodies in which virion particles are embedded, as is the case for other large dsDNA insect viruses such as baculoviruses. Due to their structural features and viral replication processes being similar to those of baculoviruses, nudiviruses were previously classified as “non-occluded baculoviruses” (NOBs) in the *Baculoviridae*. However, due to differences in morphological and genomic characters, they were later removed from the family *Baculoviridae* and orphaned for years without having a clear classification. Several nudiviruses were also characterized as “intranuclear bacilliform viruses” (IBVs) during this period. Ultimately, in 2013, the new family *Nudiviridae* was assigned by the International Committee on Taxonomy of Viruses (ICTV), consisting of two new genera, *Alphanudivirus* and *Betanudivirus*. To date, a variety of nudiviruses and nudivirus-like viruses have been reported from various host species belonging to the Lepidoptera, Trichoptera, Diptera, Siphonaptera, Hymenoptera Neuroptera, Coleoptera, Homoptera, Thysanura, Orthoptera, Acarina, Araneina, and Crustacea (Table 1).

Criteria for Classification

Although nudiviruses were first characterized according to the absence of an occlusion body, increasing numbers of the *Nudiviridae* have been found to generate occlusion bodies, so this feature is no longer suitable for classification. Several criteria have been proposed by nudivirus researchers for classifying a virus as a member of the *Nudiviridae*: (1) virion morphology is typically rod-shaped and enveloped; (2) the virus has a large circular dsDNA genome and possesses the conserved nudivirus core genes (described further below); (3) the virus propagates in the nuclei of infected host cells and induces nucleus hypertrophy; (4) the virus can be transmitted orally or parenterally; and (5) the virus infects hosts at larval and/or adult stages and exhibits diverse tissue and cell tropisms.

As most of these morphological criteria may not clearly distinguish nudiviruses from other dsDNA arthropod viruses, molecular phylogenetic analyses using genomic data have become the most reliable means of classifying nudiviruses. These viruses exhibit phylogenetic distinctiveness from their closest viral taxa, e.g., baculoviruses (see Fig. 1). Most new members of the *Nudiviridae*, either re-assigned from other virus families or new isolates, are classified based on genetic analyses in spite of their various morphologies and physiologies.

Members of the *Nudiviridae*

Table 1 lists the current well-studied or confirmed nudiviruses, though several potential nudiviruses remain to be definitively described. Current classification puts both OrNV and GbNV in the genus *Alphanudivirus*, with HzNV-1 and HzNV-2 belonging to the genus *Betanudivirus*, and the rest remaining unassigned (Fig. 1). Apart from newly isolated nudiviruses, members of the *Nudiviridae* have mostly been re-assigned from other virus families and reclassified in the *Nudiviridae*. These re-classified viruses were renamed using the species name of the host from which they were first isolated. For instance, *Oryctes rhinoceros nudivirus* is now the type species of the genus *Alphanudivirus*. OrNV, from the beetle *Oryctes rhinoceros*, is a member of that species and is first

Table 1 Nudiviruses and hosts from which they were isolated

Host		Nudivirus (abbreviation)
Order	Species (common name)	
Lepidoptera	<i>Heliothis zea</i> (corn earworm)	Heliothis zea nudivirus – 1 (HzNV – 1)
	<i>Heliothis zea</i> (corn earworm)	Heliothis zea nudivirus – 2 (HzNV – 2)
Diptera	<i>Tipula oleracea</i> (cabbage crane fly)	Tipula oleracea nudivirus (ToNV)
	<i>Tipula paludosa</i> (European crane fly)	Tipula paludosa nudivirus (TpNV)
	<i>Drosophila innubila</i> (mycophagous fly)	Drosophila innubia nudivirus (DiNV)
	<i>Drosophila melanogaster</i> (fruit fly)	Kallithea virus (KV)
Orthoptera	<i>Gryllus bimaculatus</i> (two-spotted cricket)	Gryllus bimaculatus nudivirus (GbNV)
Coleoptera	<i>Oryctes rhinoceros</i> (rhinoceros beetle)	Oryctes rhinoceros nudivirus (OrNV)
Decapoda	<i>Penaeus monodon</i> (tiger shrimp)	Penaeus monodon nudivirus (PmNV)
	<i>Litopenaeus vannamei</i> (whiteleg shrimp)	Penaeus vannamei single nucleopolyhedrovirus (PvSNPV)
	<i>Homarus gammarus</i> (European lobster)	Homarus gammarus nudivirus (HgNV)

Fig. 1 Phylogeny of large dsDNA arthropod viruses. The tree was generated by Maximum Likelihood (ML) inference analysis using a concatenated amino acid alignment of 37 nudivirus-related genes. Numbers on the nodes indicate ML non-parametric bootstrap support (100 replicates). The white spot syndrome virus (WSSV-TH) was used as the outgroup. This tree has been reproduced with permission from: Bézier, A., Thézé, J., Gavory, F., *et al.*, 2015. The genome of the nucleopolyhedrosis-causing virus from *Tipula oleracea* sheds new light on the *Nudiviridae* family. *Journal of Virology* 89, 3008–3025.

nudivirus discovered had been variously named “Rhabdionvirus oryctes”, “baculovirus of Oryctes”, or “Oryctes baculovirus” and was assigned as a subtype in different virus families, e.g., the family *Baculoviridae* Subgroup C (non-occluded rod-shaped nuclear viruses) and the Oryctes virus family. GbNV that was isolated from the two-spotted cricket, *Gryllus bimaculatus*, was previously called the “baculovirus of cricket” or “cricket baculovirus”. *Heliothis zea nudivirus* is the type species of the *Betanudivirus* genus with HzNV-1 as a member of that species. HzNV-1 was isolated from *Heliothis zea* ovarian tissue cell lines and its genome was the first nudivirus genome to be sequenced. It has variously been known as “IMC-HZ-I-NOV”, “baculovirus X”, “Hz-1 baculovirus”, and “Hz-1 virus (Hz-1V)”, and it was considered to belong to the type species of the subfamily *Nudibaculovirinae* in the *Baculoviridae*.

Reassignment of PmNV into the *Nudiviridae* was more complicated as this shrimp-infecting virus forms occlusion bodies (as do baculoviruses) and it had been designated “monodon baculovirus” (MBV), “*Penaeus monodon* baculovirus”, “*Penaeus monodon* singly enveloped nuclear polyhedrosis virus” (PmSNPV) in the subgenus of single nucleocapsid SNPVs, and “*Penaeus monodon*

nucleopolyhedrovirus" (PemoNPV) in the former *Nucleopolyhedrovirus* genus. This virus is now considered as an unclassified nudivirus belonging to the family *Nudiviridae* based on molecular phylogenetic analysis and consequently was renamed "Penaeus monodon nudivirus (PmNV)". Genomic data on PmNV supports this new classification and may even suggest that a potentially distinct genus under *Nudiviridae* should be assigned (described below). However, the name MBV is still commonly used in the literature to describe this virus. Another occluded nudivirus, TpNV, which infects crane flies, was previously named "T. paludosa baculovirus (TpBV)" and "T. paludosa nucleopolyhedrovirus (TpNPV)".

Apart from the above-mentioned nudiviruses characterized according to their structural features of the virion particle, HzNV-2 representing the second nudivirus to be isolated from the corn earworm *Heliothis zea*, which was previously named as "gonad-specific virus (GSV)", "*H. zea* reproductive virus", and "Hz-2V", primarily due to pathogenies in its hosts. Newly isolated nudiviruses are now more practically designated according to the hosts from which they have been isolated, such as DiNV that infects the mushroom-feeding fly *Drosophila innubila*, and ToNV that infects the cabbage crane fly *Tipula oleracea*. Kallithea virus (KV) is the first DNA virus to be isolated from wild *D. melanogaster* populations and has temporarily been named according to the collection locality.

Phylogeny (Evolution of *Nudiviridae* and Other dsDNA Arthropod Viruses)

Phylogenetic analyses of viral core genes (described in "Genome" section) reveals that nudiviruses can be separated from baculoviruses (Fig. 1, shaded in green). The *Nudiviridae* exhibits several clades, including from the *Alphanudivirus* and *Betanudivirus* genera. The newly sequenced PmNV and ToNV genomes suggest the existence of two additional genera. Notably, the phylogeny demonstrates that the bracoviruses (Family *Polydnviridae*) may derive from nudiviruses. Bracoviruses form a symbiotic relationship with braconid wasps and are obligatorily parasitic on their Lepidopteran hosts. The presence of a significant number of genes homologous to those of nudiviruses in bracoviruses suggests that these polydnviruses may have originated from the integration of an ancient nudivirus into the genome of a braconid wasp. Nudivirus-like genes have also been identified in *Nilaparvata lugens* endogenous nudivirus (NIENV) of the plant sap-sucking insect, *Nilaparvata lugens* (brown planthopper), but whether these genes are expressed or functional is uncertain.

The phylogeny displayed in Fig. 1 may reflect the evolution of these viruses. The common ancestor of baculoviruses and nudiviruses seems to have diverged upon the appearance of holometabolous insects (insects exhibiting completely different appearances in immature and mature stages). The baculovirus lineage became specialized in infecting larvae of the newly evolved dipteran, hymenopteran, and lepidopteran insects. In contrast, the nudivirus lineage evolved to infect larval and adult hosts from a variety of diverse arthropods and by means of complex infection strategies. Such strategies, including the establishment of latent infections, might have been instrumental for the nudiviral ancestor of the bracoviruses to integrate its genome into a parasitoid wasp chromosome.

Virion Structure

The enveloped virion of nudiviruses typically harbors a single rod-shaped nucleocapsid. The virion structures of the two recognized *Nudiviridae* genera exhibit different morphologies, with alphanudiviruses (e.g., OrNV and GbNV) having more rounded virion particles of $\sim 200 \times 100$ nm, whereas those of betanudiviruses (e.g., HzNV-1 and HzNV-2) are longer and thinner at $\sim 300\text{--}400 \times 80$ nm. Several nudiviruses exhibit protruding structures within their virions, such as that of OrNV with thickened or "capped" nucleocapsid ends and a tail-like appendage at one end of the nucleocapsid. A filamentous structure has frequently been observed between the nucleocapsids and dilated envelopes of GbNV and HzNV-2, whereas HzNV-1 does not exhibit this structure.

Although nudiviruses such as HzNV-1 and GbNV are non-occluded, many nudiviruses present occlusion body formation during viral transmission. The morphology of occlusion bodies also differs among nudiviruses. ToNV and TpNV form enveloped occlusion bodies, PmNV forms non-enveloped occlusion bodies, and both OrNV and HzNV-2 form facultative occluded virions. Although the occlusion body proteins or potential genes encoding nudivirus occlusion bodies usually bear low sequence similarities to those of baculoviruses (described further below), the similar morphologies of baculovirus and nudivirus occlusion bodies would seem to preclude using this feature as a criterion to distinguish these two families of viruses.

Transmission and Pathogenesis

Nudiviruses infect a broad diversity of host species and they exhibit tissue tropism and transmission modes distinct from those of their sister group, the baculoviruses. Unlike baculoviruses that infect primarily the midgut epithelium of lepidopteran larvae and are transmitted by feeding (*per oral* route), nudiviruses infect a variety of tissues of both larvae and adult hosts in a range of arthropod orders (Table 1), and they can be transmitted through feeding or mating (*per oral* and *per parenteral* routes, respectively). Pathogenies are therefore diverse and depend on the stage of the infected host. Specifically, OrNV infects both larvae and adult *O. rhinoceros* beetles via *per oral* transmission and targets primarily midgut epithelial cells. In larvae, the virus spreads to other tissues and causes the infected larvae to die by fat body disintegration. Infected adult beetles exhibit few obvious symptoms,

carrying abundant newly-synthesized viruses and releasing them in their feces. GbNV infects its host crickets through fecal-contaminated foods. It targets the fat body cells of cricket nymphs and adults. GbNV infection is lethal in early nymphs, whereas infected adult crickets may exhibit reduced size or become crippled. PmNV is transmitted via oral ingestion of foods contaminated with feces containing viral occlusion bodies. PmNV targets the anterior midgut epithelium of very young post-larvae of tiger shrimp. When infecting the post-larvae, juveniles and adults, PmNV targets the hepatopancreatic tubule epithelium and duct epithelium. PmNV infectivity has been shown to reduce shrimp productivity. The fly nudivirus, DiNV, diminishes the viability of infected flies and reduces the number of eggs they lay. TpNPV targets the blood cells and the infection delays the crane fly larval development before the larvae die.

Differences in the pathogenies of HzNV-1 and HzNV-2 infection are interesting. HzNV-1 can replicate in only cultured cells of lepidopteran tissue but the infection is not evident in its insect host, the corn earworm. In cultured cell lines, HzNV-1 results in productive infection which kills most of the cells, leaving very few survivals to become viral latently infected cells. During viral latency, viral DNA was found to present as an episome or as an insertion into the host's genome. In contrast, HzNV-2 can replicate and persistently infect corn earworm. The predominant means of transmission of HzNV-2 is through mating between infected moths. HzNV-2 infects the reproductive tissues of infected moths, causing malformation of those tissues and host sterility. The mating pheromone generated by infected females attracts mate-seeking males, further transmitting the HzNV-2 nudivirus.

Virus Life Cycle

Viral life cycles in infected cells have been studied for only a few nudiviruses. OrNV attaches to and enters cultured cells by pinocytosis, whereby the virus is brought into cells by means of a small vesicle formed by cell membrane invagination. OrNV may enter the nucleus in the form of an unenveloped nucleocapsid, although the uncoating process in the cytoplasm remains unknown. Initial virus replication occurs at ~7 h post infection (hpi) with a sign of cleared chromatin-free areas showing up in the nucleus. In these areas, envelopes and nucleocapsid shells form first, and the viral nucleoprotein core and DNA condense into these enveloped shells. As early as 12 hpi, the resulting virions enter the cytoplasm and bud out through the plasma membrane, where they acquire a second membrane. Viral budding is greatest at 16 hpi and lasts until at least 36 hpi. The assembly processes of OrNV and some nudiviruses are very different from baculoviruses; baculoviruses produce naked nucleocapsids in the nucleus and acquire their envelopes during budding from the plasma membrane or before occlusion into polyhedra or granule cores. In OrNV-infected cells, enveloped nucleocapsids have always been observed although the virus purified from the cells with only a single envelope exhibits similar infectivity as the virus acquiring a second envelope by budding.

In the cell line DSIR-HA-1179, OrNV produces at least 27 proteins of which 14 are thought to be envelope proteins and 13 are associated with the nucleocapsid. The most abundant protein, P13, can be synthesized up to 36 hpi but most of the protein syntheses have ceased before it. Although the homologs of late or very-late genes appear in the genome, synthesis of these late proteins does not occur in OrNV.

HzNV-1 exhibits two infection stages in cultured cells, i.e., productive (lytic) and persistent (latent) infections (**Fig. 2**). DNA replication and virus assembly processes in productive infection of HzNV-1 are similar to those of OrNV. That is, enveloped, rod-shaped virus particles are first formed in the nucleus of infected cells and then filled with capsids containing the viral DNA. Viruses are released from infected cells by cell lysis. The early sign of viral DNA replication occurs at 4 hpi, and the replication cycle can be divided into three stages based on the timing that viral proteins appear: early (0–4 hpi), intermediate (4–8 hpi), and late (beyond 8 hpi). As high titers of virus progeny are produced, most infected cells ultimately die. However, a small percentage (usually less than 5%) of infected cells become persistently infected. During this stage, virus progenies are detected with low titers for a prolonged period of time and for many culture passages without obvious cell lysis. The persistently infected cells can be established by the viruses in both productive and latent infection cycles. Upon the establishment of persistent viral infection, virions are not detectable in most of the infected cells and viruses exist either as episomes or are inserted into the host genome (**Fig. 2**). At the same time, in some very few cells (less than 0.2%), viruses undergo the productive viral infection cycle, resulting in viral titers of approximately 10^3 plaque-forming unit (PFU)/ML in the culture medium. The phenomenon of HzNV-1 persistent infection is more appropriate to be described as a latent infection, in which virus is usually undetectable, and intermittent acute symptoms may occur in infected cells or tissues. During latency, insect cells are resistant to infection with homologous viruses (the same viruses), but they can be reactivated to result in a productive infection by infecting them with heterologous viruses (different viruses).

After several serial, high-multiplicity passages of HzNV-1 virus in cell culture, defective interfering particles (DIPs) show up in the culture. These particles contain smaller genomes, which might be acquired from deletions in the HzNV-1 genome. Interestingly, 37 HzNV-1 viral proteins identified in virus with a complete genome are all synthesized by DIPs, but the relative rates of synthesis of many of these proteins are altered in DIPs (thirteen decelerate and five accelerate). The contribution of DIPs to the establishment of latency remains unknown. Temporal gene expression profiles have also been analyzed for HzNV-1. During productive infection, gene expression can be categorized into early stage (0–2 hpi), intermediate stage (2–6 hpi), and late stage (after 6 hpi), with at least 101 transcripts expressed; during latent infection, there is only one detectable transcript, i.e., the persistency-associated transcript 1 (PAT1) that is expressed by the *persistence-associated gene 1* (*pag1*).

Fig. 2 Bi-phasic infection of HzNV-1 in insect cells. After HzNV-1 enters the infected cell, the virus may be uncoated and enter the nucleus in the form of an unenveloped nucleocapsid. In the nucleus, the viral DNA may insert into the host chromosomal DNA or exist as episomes for latent infection. In this infection stage, viral particles are not detectable and only the *pag1* gene expresses its transcript. Occasionally, HzNV-1 switches to productive infection in which viral DNA and proteins are abundantly produced. The enveloped, rod-shaped viral nucleocapsids are formed and filled with viral DNA in the nucleus. Viruses obtain their second envelope from the plasma membrane when they bud out from the cell. The budding eventually leads to the lysis of the infected cell.

Table 2 Comparison of nudivirus genomes

Virus	Genome size (base pairs)	No. of ORFs ^a	G + C content (%)	Gene density (per kilobase pairs)
HzNV – 1	228,089	155	41.8	1.47
HzNV – 2	231,621	113	42.0	2.05
OrNV	127,615	139	42.0	0.92
GbNV	96,944	98	28.0	0.99
PmNV	119,638	115	34.5	1.04
ToNV	145,704	131	25.5	1.11
DiNV	155,555	107	30.0	1.45
KV	152,388	95	38.9	1.60
HgNV	107,063	97	35.3	1.10

Genome

General Features

Nudiviruses whose genomes have been fully sequenced are listed in [Table 2](#). These viral genomes vary greatly in size, G + C content, and number of coding sequences, except for the genomes of HzNV-1 and HzNV-2 that share 94% sequence identity. G + C contents of some nudivirus genomes, e.g., GbNV and ToNV, are particularly low, with a lowest for ToNV at 25.5%. Similar to other large dsDNA viruses, nudivirus genomes feature direct repeat sequences that are extremely AT-rich (up to 98%) and with 2–3 copies of short reiterated sequences. However, these direct repeats are not homologous to each other within or between nudivirus genomes, or with those of other large dsDNA viruses. Numbers of direct repeats also differ among nudivirus genomes.

Table 3 The conserved baculovirus core genes in nudivirus genomes

Gene name	Encoding product
<i>dnapol</i>	DNA polymerase
<i>helicase</i>	Helicase
<i>p47</i> , <i>lef-4</i> , <i>lef-8</i> , <i>lef-9</i>	RNA polymerase subunit
<i>lef-5</i>	Late expression factor
<i>vlf-1</i>	Very late expression factor
<i>p74</i> (<i>pif-0</i>), <i>pif-1</i> , <i>pif-2</i> , <i>pif-3</i> , 19 kDa (<i>pif-4</i>), <i>odv-e56</i> (<i>pif-5</i>), <i>ac68</i> (<i>pif-6</i>), <i>vp91</i> (<i>pif-7</i>)	<i>per os</i> infectivity factor (PIF)
<i>vp39</i>	Major capsid protein
<i>38 K</i>	Viral phosphatase
<i>p33</i>	Sulfhydryl oxidase
<i>ac81</i>	Unknown function

For instance, the HzNV-2 genome harbors six direct repeats, the ToNV genome has five, the GbNV genome contains 14, and the DiNV genome has 156 simple direct repeats that account for 5.1% of the genome. Homologous repeat regions composed of direct repeats but with an imperfect palindromic core sequence commonly exist in the genomes of baculoviruses. In contrast, no homologous repeats have been found in most sequenced nudivirus genomes, apart from in the ToNV genome that hosts several direct repeats containing imperfect palindromic cores that are reminiscent of homologous repeats.

Gene Content

Nudivirus genomes typically share a set of 30–32 common genes, so-called “nudivirus core genes”. Although the members of these nudivirus core genes are likely to be debated as more nudivirus genomes become available, currently 20 nudivirus core genes homologous to baculovirus core genes (Table 3) are present in the nudivirus genomes sequenced to date. These genes are responsible for different functions in both baculovirus and nudivirus life cycles. Their presence evidences the close relationship between nudiviruses and baculoviruses, but phylogenetic analyses of these genes also support their divergence (described in “Phylogeny (Evolution of Nudiviridae and Other dsDNA Arthropod Viruses)” section).

Among the 20 nudivirus core genes shared with baculoviruses, eight encode homologs of baculovirus *per os* infectivity factor (PIF). PIFs are conserved among all baculoviruses and are essential for oral infection of insect hosts. Since many nudiviruses also exhibit *per oral* transmission, the occurrence of baculovirus PIF homologs suggests that a conserved infection mode exists in both nudiviruses and baculoviruses.

Genes encoding the four RNA polymerase units homologous to baculovirus variants – P47, LEF-4, LEF-8, and LEF-9 – are also present among the nudivirus core genes, as is a late expression factor, LEF-5, and a very late expression factor, VLEF-1. Thus, nudiviruses seem to have a baculovirus-like RNA transcription apparatus and transcribe late gene expression in a similar manner to baculoviruses.

Aside from these 20 shared core genes, some nudiviruses present a gene homolog to the baculovirus *polyhedrin/granulin* (*polh/gran*) gene. In baculoviruses, *polh/gran* encodes the polyhedrin protein that forms the occlusion body. The ToNV nudivirus obligatorily forms occlusion bodies, and its occlusion body protein is encoded by a baculovirus *polh* homolog. However, the gene encoding the major occlusion body protein of another occluded nudivirus, PmNV, does not share sequence similarities to baculovirus *polh* or *gran*. Whether the occlusion bodies of other occluded nudiviruses are encoded by *polh/gran* homologs awaits investigation.

Apart from genes encoding protein products, nudiviruses such as HzNV-1 and KV encode miRNAs. miRNAs are involved in the establishment of HzNV-1 latency and regulation of host histone modification. KV transcribes many small RNAs (21 nucleotides) during infection of *D. melanogaster*. These small RNAs may be the targets of *Drosophila* antiviral RNA interference (RNAi) responses.

Gene Regulation for Switching Productive and Latent Infections

The molecular mechanism responsible for switching between productive and latent infections has been analyzed for HzNV-1. A 6.2-kilobase early transcript encoded by the *hhi1* gene reactivates viruses from latently infected cells. The *hhi1* transcript has been detected very early during productive HzNV-1 virus infection, but it is not detectable during latent infection. When *hhi1* is expressed in latently infected cells, most of the cells lyse and release high titers of viral progeny. In contrast, when *hhi1* expression is suppressed (e.g., by siRNA), the number of latently infected cell clones is dramatically increased. The expression of *hhi1* transactivates the expression of viral early genes, which may contribute to switching the virus from latent infection to productive infection. Latency of HzNV-1 is also well regulated at the molecular level. During viral latency, the non-coding RNA PAT1 (transcribed by *pag1*) is the only detectable viral transcript. PAT1 constantly exists in both latent and productive infections. Overexpression of PAT1 in productively infected cells enhances HzNV-1 latent viral infection. Interestingly, *pag1* encodes at least two miRNAs that target the *hhi1* coding region. Both of these miRNAs can reduce the amount of *hhi1* transcript within cells to establish latent viral infection. The interactions between *hhi1* and *pag1* are illustrated in Fig. 3. During HzNV-1 infection, cells

Fig. 3 Model for the establishment of productive or latent HzNV-1 viral infection via *hhi1* and *pag1* interactions. (a) Infection of HzNV-1 results in high levels of *hhi1* expression, and a moderate level of *pag1* expression. The abundant *hhi1* transcript can tolerate the RNA degradation caused by the *pag1* miRNAs, and transactivate viral early genes for activating the productive infection in most of the infected cells. (b) In a low percentage of cells, the level of *hhi1* transcript is low or undetectable. Suppression of *hhi1* transcript by *pag1* miRNA allows the virus to enter latency. (c) Viruses in the latently infected cells can be reactivated by introducing *hhi1* transcript, which results in virus production and cell lysis.

exhibiting high levels of *hhi1* expression can tolerate the RNA degradation caused by the *pag1* miRNAs and enter productive viral infection (Fig. 3(a)). However, if the expression level of *hhi1* in a cell becomes lower, or if *pag1* miRNAs are introduced, *hhi1* transcript expression will be suppressed by *pag1* via miRNA degradation and the virus enters latency (Fig. 3(b)). Re-activation of latent virus can be induced by introducing *hhi1* transcripts, resulting in virus production (Fig. 3(c)).

Negative Impacts and Potential Applications

PmNV infection was first identified in Taiwanese shrimp in 1977 and has since been reported worldwide. The infection of PmNV was initially thought to have resulted in the collapse of the penaeid shrimp culture industry in Taiwan in 1988. Although subsequent analyses suggested the collapse may have been due to environmental management or infection by other pathogens, PmNV is still closely linked to losses in many shrimp culture facilities in Taiwan and the Indo-Pacific region. To control PmNV infection, infected stocks need to be eradicated and the hatcheries must be disinfected using chemicals such as formalin, chlorine, and iodophor at sufficient concentrations.

Use of OrNV as a biocontrol agent to suppress its beetle host *O. rhinoceros* is a classical but rare example of (initially) successful biological control. *O. rhinoceros* damaged both coconut and oil palms in many Pacific islands in the early 1900s. OrNV was first used in Samoan fields in 1967 to control this beetle. Symptomless adult beetles infected with the nudivirus become natural vectors for OrNV spread, and beetle populations were effectively under control for over 30 years. However, a new wave of invasive *O. rhinoceros* became established in 2007 that were resistant to OrNV infection. Since resistant beetles had already been detected in 1989, it is unclear if the OrNV biocontrol process catalyzed the emerging resistance in *O. rhinoceros*.

Glossary

Ambisense and monosense An ambisense single-stranded RNA virus (as in segmented negative stranded viruses) refers to a virus in which both the –ve and +ve sense RNA segments encode proteins. For the ssDNA parvoviruses both the +ve, and its –ve copy, ssDNA genomes are packaged and, after conversion to a dsDNA in the recipient host, encode mRNAs and proteins. In contrast, for monosense ssDNA parvoviruses, genes are located on only the -ve strands that are predominantly packaged.

APOBEC ("apolipoprotein B mRNA editing enzyme, catalytic polypeptide-like") is a family of evolutionarily conserved cytidine deaminases. A mechanism of generating protein diversity is mRNA editing as well hypermutation.

EVE-derived immunity (EDI) widespread recruitment of endogenous viruses as regulatory elements for immune genes that points to a systematic evolutionary process in their co-option for host immunity.

Monophyly Members of a monophyletic taxon are all descendants of one common ancestor. Modern taxonomy aims to establish exclusively monophyletic taxa. A good example is the vertebrate taxon of amniotes, unifying mammals, birds and reptiles.

Paraphyly A taxon is considered paraphyletic if it excludes at least one lineage from its definition, even though given excluded lineage(s) still clearly derive(s) from the same common ancestor as the lineages included in the defined taxon. A well-known example is the definition of reptiles as taxon without the inclusion of birds.

Polyphyly A taxon is polyphyletic if it includes lineages derived from a common ancestor, which itself is excluded from the taxon definition. Warm-blooded animals make a good example, as it unifies birds and mammals but excludes reptiles, though all three derive from the same reptile-like common amniote ancestor.

Introduction

Parvoviruses of invertebrates are named densoviruses (DVs, formerly denso-nucleosis viruses or DNVs) although their demarcation characteristics from vertebrate parvoviruses (PVs) are increasingly blurred through the discovery of a third lineage (now classified as subfamily *Hamaparvovirinae*), which encompasses both vertebrate and invertebrate parvoviruses and is related to several endogenous viral elements (EVEs) identified as integration into the genomes of members from all major arthropod lineages. Linear single-stranded DNA (ssDNA) virus families of animals are relatively scarce since: (1) ssDNA cannot be transcribed to yield translation products such as a viral DNA polymerase; (2) linear ssDNA cannot, in contrast to linear single-stranded RNA, be replicated without loss of genome termini (corresponding to Okazaki fragments) of genomic integrity unless complex hairpin structures, or a protein-primed mechanism, are introduced to create double-stranded DNA first; (3) the absence of a complementary DNA strand, as a repair template, increases the mutation rate, and therefore limits the maximum length (2–12 kb with very few exceptions; to that of RNA viruses. PVs and DVs have small icosahedral capsids with a diameter of 18–27 nm with a limited packaging capacity). Although most DVs are highly pathogenic, some are essential for the life cycle of their hosts. Infection with *Dysaphis plantaginea* densovirus (DpIDV) is required to produce the winged morph in asexual clones of the rosy apple aphid and its colony dispersal to neighboring plants. This mutualistic relationship between the rosy apple aphid and its viruses results both in a negative impact of DpIDV on rosy apple aphid reproduction, but also contributes to the survival of aphids by inducing wing development and promoting dispersal.

The ssDNA viruses are, apart from those of the bidnaviruses, exceptionally widespread in all domains of life despite the limited number of virus families. Metagenomic studies dramatically boosted our knowledge about the distribution of ssDNA viruses in the biosphere, from the human gut to hot springs. The diversity of ssDNA viruses appears to be determined by two principal factors: extremely high nucleotide substitution rates that approach those of RNA viruses, facilitating adaptation to different environments and pervasive recombination, both by DNA and RNA donors.

¹This article is dedicated to Prof. Michael Rossmann for his essential contributions to the structure of arthropod densoviruses and to Prof. Su De Ming, a pioneer of parvovirology in China. Both forerunners passed away while this article was in preparation.

Discovery, Taxonomy and Evolution of Densoviruses; of Polyphyly, Paraphyly and its Tangled Relationship With Vertebrate-Infecting Parvoviruses

DVs are defined as small icosahedral viruses containing a linear, monopartite, ssDNA genome with terminal hairpins which facilitate rolling hairpin replication (RHR). DV genomes are monopartite, though for the ambidensoviruses both + and – ssDNA strands are coding in an ambisense strategy.

The first discovery of a DV was in the early 1960s when an epizootic decimated a mass rearing of *Galleria mellonella* L. larvae, reared as fishing bait in France. Electron microscopic examination of thin sections from diseased larvae revealed hypertrophied nuclei containing an electron-dense viroplasm with thousands of tiny viral particles. After purification, these particles were observed as small isometric, nonenveloped virions, 22–25 nm in diameter, and their biochemical analysis showed that they contained single-stranded DNA. The virus causing the disease was designated as densovirus, which later was simplified to the name densovirus (DV). Diseases presenting the same type of histopathological features, and caused by the same type of viruses, were later described not only in Lepidoptera but also in other invertebrates. The cloning and sequencing of many DV genomes during the last two decades, while confirming their relatedness to the vertebrate parvoviruses, revealed an extraordinary diversity, reflecting very likely the evolutionary diversity of their hosts. To date, and despite the current *Parvoviridae* taxonomy which reflects the actual evolutionary relationships among the family members, regardless of host affiliation, parvoviruses (family *Parvoviridae*) infecting vertebrates are still referred to as parvoviruses and parvoviruses of invertebrates are traditionally united under the densovirus designation even though this kind of classification of the family would introduce polyphyly. In contrast to most DNA viruses, DVs lack the DNA polymerase gene and use a pleiotropic non-structural protein 1 (named NS1 or Rep) for Rolling-Hairpin Replication (RHR).

It became apparent throughout the *Parvoviridae* family that the SF3 helicase superfamily domain of the NS1 is the only conserved motif at the protein sequence level, hence NS1-based phylogeny was introduced as a basis of classification since 2014. Although this method initially conformed with the segregation of the family into subfamilies *Parvovirinae* and *Densovirinae* (sensu lato; referring to all invertebrate parvoviruses at the time), following the vertebrate-invertebrate host affiliation-based classification, the discovery of the first members from the current invertebrate-infecting genera *Brevihamaparvovirus*, *Penstylhamaparvovirus*, and *Hepanhamaparvovirus* revealed a diversity among densoviruses, which was unmatched with the rather well-conserved nature of the vertebrate-infecting *Parvovirinae*. Members of the latter share both NS1 and VP proteins of a clearly homologous nature proven by detectable sequence similarity, throughout basically the entire length of these proteins. In contrast, densoviruses could be linked together only by the above-mentioned short (approx. 200 aa long) SF3 helicase domain of detectable sequence similarity. If only the helicase domain is considered, however, certain densoviruses, such as hepanhamaparvoviruses, harbor the same amount of amino acid (aa) sequence similarity to certain densoviruses as they do to members of the vertebrate *Parvovirinae*.

Since 2012 and on a frequent basis, parvoviruses of a novel, divergent lineage, unified under the name “chapparvovirus”, have been detected in association with kidney and liver tissue, as well as with various secretions (such as blood) and excretions (outbreaks of enteritis) of vertebrates. As unexpected as it may be, nevertheless, phylogeny evidence revealed a close relationship of these vertebrate-infecting parvoviruses to invertebrate-infecting densoviruses, such as members of genera *Hepanhamaparvovirus*, *Penstylhamaparvovirus*, and *Brevihamaparvovirus*. To further complicate the situation, EVEs have been detected in arachnid, chilopod, entognath and coleopteran arthropod genomes, evidently derived from ancient members of the “chapparvovirus” lineage, previously believed to be yet another new genus of *Parvovirinae*. These findings led to the establishment of the first *Parvoviridae* family of mixed host affiliation, designated *Hamaparvovirinae*. Although the subfamily itself is well-supported, *Hamaparvovirinae* still appears to be the most heterogeneous one of the three subfamilies, as relationships between its three major clades, namely *Penstylhamaparvovirus*-*Brevihamaparvovirus* vs. *Hepanhamaparvovirus* and affiliated unclassified relatives vs. *Ichthamaparvovirus* and *Chaphamaparvovirus* have low support and they lack homologous capsid protein sequences (Fig. 1). This could suggest that *Hamaparvovirinae* may not be long-lived once novel parvoviruses related to these three clades will be discovered and provide more insights into evolutionary relationships within this diverse clade.

Back in 2014, the unification of several ambisense densovirus genera to establish the large and diverse genus, called Ambidensovirus, created another major, unforeseen problem. Even then Ambidensovirus did not conform with the then-established demarcation criteria, albeit the ambisense genome organization proved to be a strong enough argument to support its existence. Since then, however, multiple densoviruses have been described, eventually rendering Ambidensovirus paraphyletic as opposed to monophyletic, as some members were more closely related to monosense iteradensoviruses than they are to other ambidensoviruses. This suggests that the orientation of the genome coding order is subjected to plasticity and either the monosense or the ambisense strategy could probably be “re-invented” on multiple occasions (Fig. 1). The selective constraints driving this conversion, however, are not well-understood. Today, to reflect the diversity of the clade and to avoid the above-mentioned paraphyly problem, ambisense DVs segregate into seven genera, namely *Miniambidensovirus*, *Protoambidensovirus*, *Aquambidensovirus*, *Scindoambidensovirus*, *Hemiambidensovirus*, *Blattambidensovirus*, *Pefuambidensovirus*.

Despite the divergence in genome organization, members of the above-mentioned seven genera and *Iteradensovirus* share some features in common with each other but not with members of any other genus in the *Parvoviridae*, including (1) a shared NS1-based and helicase domain-based phylogeny; (2) their VP proteins appear to share a common ancestral VP protein gene and similar capsid structures; (3) at least 32% identity can be detected between the NS1 proteins of any itera- or ambidensovirus, but only much lower identities with other densoviruses; (4) possession of a phospholipase A2 (PLA2) domain in their largest minor capsid protein sequence. Based on these criteria, ambisense DVs and monosense iteradensoviruses are now united in one

Fig. 1 Bayesian phylogenetic inference of family *Parvoviridae* based on the SF3 helicase domain. For the easier visibility subfamily *Parvovirinae* has been collapsed. Each tip label represents a separate species of its assigned genus (though murine chapparravirus is the same species as mouse kidney parvovirus). The current (2020) taxonomy is presented as branch labels, subfamily level taxonomy is presented to the right. Blue branches indicate lineages, which lack the phospholipase A2 domain from their large minor structural proteins. Branches presented in multiple colors correspond with genera introduced by the 2020 new taxonomy to resolve the former paraphyletic situation of ambisense densoviruses, previously classified as one genus. Ambisense genome organization is indicated by two small arrows facing toward each other. Host spectrum of each species or subfamily is indicated by the silhouette of the host animal. The reliability of the topology is indicated by posterior probability values, represented by the circles at the nodes; the larger and redder a circle is the higher the support is of given node as bright, large red circles indicate maximal support. This figure was created by BEAST v1.10.4.

subfamily on their own, which is subfamily *Densovirinae*. Given the large number of EVEs, discovered in various invertebrate genomes, which appear to be closely-related to this clade, it is to be expected that the current eight genera will soon be accompanied by several new ones, when the current dynamics of virus discovery are considered. The current taxonomy of DVs is summarized by [Table 1](#).

Biology, Pathology and Host Range

So far, DVs have been found in almost all major clades of the phylum Arthropoda, including arachnids, diplopods, decapod crustaceans and hexapods. As of the latter two, six different insect orders, as well as penaeid shrimps (family Penaeidae), crabs, and a crayfish (*Cherax quadricarinatus*) are known to be infected by DVs. Recent studies have derived DVs from members of the vast and diverse phylum of Mollusca, infecting oysters. The DV host spectrum also spans deuterostome invertebrates, derived from sea stars

Table 1 Master list of densovirus species. Former classification (Cotmore *et al.*, 2019): rows 1: Ambidensovirus, rows 2 Brevidensovirus, rows 3 Hepandensovirus, row 4 Iteradensovirus and row 5 Penstyldensovirus with acronyms and GenBank accession numbers. References are to be found in the GenBank listings. Revision of the family, accepted in 2020 (Penzes *et al.*, 2020): subfamily a: *Densovirinae* with ambidensoviruses, in the former genus *Ambidensovirus* (i) and genus *Iteradensovirus* (ii) and subfamily b: *Hamaparvovirinae* with genera *Brevihamaparvovirus* (x), *Hepanhamaparvovirus* (y), *Penstylghamaparvovirus* (z). The 4th column contains the names of the proposed genera of ambisense densoviruses

and sea urchins (phylum Echinodermata). Moreover, using a metagenomic approach, DVs have been derived from eumetazoan animals even a primitive as cnidarians while the presence of endogenous DV-like elements in nematodes and platyhelminths implies that the DV host spectrum, in fact, might span most eumetazoan invertebrate phyla. DVs, which have been characterized thoroughly, were derived mainly from insects (orders Lepidoptera, Diptera, Hymenoptera (e.g., red imported fire) Blattodea, Hemiptera and Orthoptera but also decapod crustaceans (giant tiger prawn, crayfish), and echinoderms (starfish and sea urchins)).

However, our knowledge on the true extent of the DV host spectrum is still limited. Invertebrates comprise multiple phyla and constitute over 1 million species. Moreover, some species, e.g., the common house cricket, are infected by at least four different ssDNA viruses. Phylogenetic analysis revealed that these densoviruses may be as diverse as their hosts, therefore a definite classification is not yet possible (Fig. 1). The hypertrophied nuclei intensively stained by Feulgen reagent is a salient feature shared by all densovirus-infected tissues to date, where characterized. Thin sections of heavily infected cells observed by EM show hypertrophied nuclei filled by a virogenic stroma containing thousands of virions and cytoplasmic paracrystalline virion arrays.

General Features

Most of the DVs so far isolated are lethal for their natural hosts, the first symptoms being anorexia and lethargy followed by flaccidity. After a progressive paralysis, a slow melanization and death follow. The smokybrown cockroach (*Periplaneta fuliginosa*), infected by PfDV, displays characteristic hind leg paralysis, uncoordinated movements and a hypertrophied abdomen. The oil palm pests *Casphalia extranea* and *Sibine fusca* (in Ivory Coast and Colombia, respectively), when infected with CeDV and SfDV display tumor lesions in the gut. Infections are highly contagious and rapidly spread leading to severe epizootics both in noxious insects such as lepidopteran defoliators, mosquito larvae, aphids or cockroaches but also unfortunately in mass rearing facilities of commercially significant invertebrates such as *Bombyx mori* in sericulture farms, crickets in cricket farms and industrial shrimp farming. A densovirus is the causative agent of the recent extensive outbreak of sea-star wasting disease (SSWD). Due to their high pathogenicity, DVs have been successfully used to control Limacodidae larvae in oil palm plantations.

Most DVs are polytropic and infect the fat body, hypodermis, central nervous system, silk gland, muscular membrane, tracheal cells, Malpighian tubules, foregut, hindgut, hemocytes, ovaries, and molting glands but not the midgut. However, some iteradenosoviruses such as BmDV (*B. mori*), CeDV (*Casphalia extranea*) and SfDV (*Sibine fusca*), multiply predominantly in the midgut.

BmBDV, though not a densovirus, is a bidnavirus which causes fatal flacherie disease in the silkworm, replicates in contrast to most parvo-like densoviruses, but similarly to BmDV, only in midgut columnar cells. *B. mandarina* and *B. mori* are considered to have a common ancestor and both (at least native strains) are susceptible to BmBDV. Many Japanese strains acquired BmBDV-resistance through improved breeding. These resistant strains became susceptible to the parvovirus-like BmDV. The bidnavirus BmBDV is, therefore, likely the native disease of *Bombyx*, whereas the origin of BmDV is likely to be a pathogen from other insects. The pyralid *Glyphodes pyloalis*, a pest of mulberry plantations of sericultural farms is also susceptible to BmDV and probably the real/original host of BmDV.

The host range of the different DVs varies considerably. Some, like GmDV of *Galleria mellonella*, and CeDV are restricted to their original hosts, some, like AdDV of *Acheta domestica* and PfDV of *P. fuliginosa* to closely related hosts while others, e.g., Junonia coenia densovirus (JcDV), Mythimna loreyi densovirus (MlDV) and the mosquito DVs infect many different host species. Although those infecting the midgut have a restricted host range, the inverse is not true for the polytropic viruses. Mosquito larvae infected with mosquito DVs exhibit symptoms of paralysis. Mosquito cells cultured in vitro often contain DVs, despite the lack of cytopathic effects (CPE), that are pathogenic for mosquito larvae by per os infection. The Ld652 cell line derived from the gypsy moth (*Lymantria dispar*) also seems to be contaminated with a DV despite the lack of a CPE. Iteradenosoviruses replicate essentially in the columnar cells of midgut epithelium. Hepadenosoviruses (genus *Hepanhamaparvovirus*) of penaeid shrimps infect hepatopancreatic tubule epithelial cells characterized by basophilic intranuclear inclusions. The penstylidenosoviruses (genus *Penstylhamaparvovirus*) are cosmopolitan and infect different species of several penaeid shrimp genera.

Densoviruses do not infect vertebrates or cells derived from vertebrates, nor was any pathogenic effect observed after inoculation of rabbits or mice with these viruses. However, their ability to integrate into the host chromosome has been exploited for stable expression of foreign proteins in insect cells and somatic transformation of insects.

Shrimp Densoviruses

Two groups (genera) of shrimp densoviruses were identified as pathogens responsible for economically significant and virulent disease in farmed shrimp (infectious hypodermal and hematopoietic necrosis virus, PstDV1) and *Fenneropenaeus chinensis* hepadenosovirus (FchDV), now both members of the *Hamaparvovirinae* subfamily. They are widespread in nature but are no longer a major economic problem because tolerant shrimp populations have been developed.

Penaeus stylirostris penstylidensovirus 1 (PstDV1)

Penaeus stylirostris penstylidensovirus 1 (PstDV1) (genus *Penstylhamaparvovirus*) was originally discovered in cultured blue shrimp (*Penaeus stylirostris*) in Hawaii in 1981. Formerly known as infectious hypodermal and hematopoietic necrosis virus (IHNV), PstDV1 causes acute infection with up to 100% mortality in *P. stylirostris*. In Pacific white shrimp *P. vannamei* and giant tiger prawn (*P. monodon*), infection is mostly chronic and results in stunted growth and runt deformity syndrome (RDS) with wrinkled antennae, cuticular deformities of the rostrums and deformed sixth abdominal segments.

PstDV1 was reported to infect various decapod species of the Penaeidae family, from wild to cultured shrimps worldwide. Only *P. merguensis* seems to be refractory to PstDV infection. PstDV1 infection occurred in all stages of the shrimp life cycle, including eggs, larvae, postlarvae, juveniles, and adults. Histologic and in-situ hybridization analysis showed Cowdrey type A inclusion

bodies in ectodermal and mesodermal tissues of penaeids such as gills, cuticular epidermis, lymphoid organs, hematopoietic tissues, antennal glands and connective tissues.

PstDV1-related EVE sequences, lacking telomers, have been detected in the germline of *P. monodon* in Australia, Madagascar and Thailand. These would likely have been eliminated unless they provide beneficial effects, such as EVE-derived immunity (EDI, e.g., mediated by TRIM5a and APOBEC).

***Fenneropenaeus chinensis* hepadensovirus (FcHVD)**

FcHVD or previously named hepatopancreatic parvovirus (HPV) (genus *Hepanhamaparvovirus*) was first reported in banana shrimp, *P. merguensis*, and in Indian prawns, *P. indicus*, in Singapore. FcHVD later was found to infect *P. chinensis*, *P. monodon* and many other penaeid species worldwide in Asia, Australia, America, and Africa. The virus was also reported in giant freshwater prawn.

Infected shrimps do not always show diagnostic gross signs of FcHVD disease, but infection is associated with reduced growth rate in juveniles and can cause chronic mortalities at early- and post-larva stages. FcHVD infected shrimps appear to be more susceptible to other viral disease agents such as White Spot Syndrome Virus (WSSV) or, *Penaeus monodon* nudivirus (previously called, erroneously, *Monodon Baculovirus* (MBV)). Target tissues for viral replication include the hepatopancreas system and the tubule epithelial cells of the digestive gland.

Transmission routes of PstDV1 and FcHVD can be either horizontal or vertical. Horizontal transmission is by cannibalism or by water contamination and vertical transmission is via infected eggs. Multiple infection with different viruses is commonly found in cultured shrimps.

New invertebrate DVs

Sea stars, infected with sea star-associated densovirus (SsaDV), inhabiting the Northeast Pacific Coast have recently experienced an extensive outbreak of wasting disease, leading to their degradation and disappearance from many coastal areas. The signs of the disease are behavioral changes, lesions, loss of turgor, limb autotomy, and death characterized by rapid degradation. SsaDV could be detected in plankton, sediments and in nonasteroid echinoderms, providing a possible mechanism for viral spread. SsaDV was detected in museum specimens of asteroids from 1942, suggesting that it has been present on the North American Pacific Coast. Since June 2013, millions of sea stars (asteroids) off the west coast of North America have wasted away into slime and ossicle piles, due to the disease known as sea-star wasting disease (SSWD). SsaDV is related to densoviruses in the Hawaiian sea urchins (Echinoidea) *Colobocentrotus atratus*, *Echinometra mathaei*, and *Tripneustes gratilla*, placing it to the same species with other DVs of echinoderms.

Cherax quadricarinatus densovirus (CqDV), the causative agent of an epizootic in freshwater crayfish *Cherax quadricarinatus*, in Australia, has a large, ambisense genome of 6334 nt. It is closely related to the marine sea star densovirus (75% identity) and is the first ambidensovirus to be found in decapod crustaceans. Mortalities after infection with CqDV occurred over 4 weeks, with up to 96% cumulative mortalities in two earthen ponds stocked with juveniles. The crayfish were weak, anorexic and lethargic. A transmission trial was conducted, using filtered, cell-free extract prepared from infected crayfish as inoculum. The disease was reproduced, with ongoing mortalities occurring in inoculated crayfish over 55 days. Experimentally inoculated crayfish showed gross signs of malaise, anorexia, and disorientation before dying. Two types of intranuclear inclusion bodies (INIBs) were seen in tissues of endodermal, ectodermal and mesodermal origin by light microscopy with hematoxylin and eosin (H&E) stained sections.

Using metagenomics, densoviral nucleic acids in oysters (*Crassostrea ariakensis*) was identified, designated CaaDV1 and CaaDV2, assembling the nearly complete genome of both (5860 nucleotides (nt) and 4034 nt, respectively). Both genomes displayed an ambisense organization but were divergent from the existing densoviral species. The NS1 protein of the two CaaDVs shared 43.3% ~ 61.5% amino acid identities with SsaDV and CqDV as well as clustering with these in phylogeny calculations. The CaaDVs are potential new members of genus *Aquambidensovirus*, accompanying the echinoderm DVs and CqDV, all of aquatic host origin.

Solenopsis invicta densovirus (SiDV) was the first DNA virus discovered in fire ants from Argentina and is related to AddV and PcDV. The red fire ant, *Solenopsis invicta* (Buren) was introduced into the United States and due to the paucity of natural enemies is estimated to cause damage of about 6 billion USD annually. SiDV causes a high mortality rate and is a prime candidate for biological control.

Recently, a metagenomic study has derived partial DV genomes from several novel invertebrate hosts, of various, distant arthropod orders. All sequences encompassed at least the complete NS1-encoding open reading frame (ORF). Myriapoda DV 1 and 2 are DVs detected in diplopods for the first time and appear to be closely-related to mosquito-infecting brevidensoviruses (genus *Brevihamaparvovirus*). *Perisesarma bidens* hepadensovirus could be a potential member of the *Hepanhamaparvovirus* genus, the first one, which is not associated with penaeid shrimps, but with the red-clawed crab (*Perisesarma bidens*), another decapod species, instead. The partially sequenced genome of *Tetragnatha maxillosa* DV which is derived from the long-jawed orb weaver (*Tetragnatha maxillosa*), suggests it is a novel arachnid DV, probably a divergent member of the *Densovirinae* subfamily.

Biochemical Properties and Purification of Densoviruses

Infectious particles of DVs are stable in a broad pH range from 3 to 9 in various buffers, and at 56°C for 60 min, except for GmDV (rapidly loses viral infectivity when raising temperature over 56°C). Therefore, DVs are still infectious and survive for a long

period in the environment. Purified virus stocks can be stored at -20°C in Tris-Cl buffer pH 7.6 without significant loss of viral infectivity for years.

The virions lack lipids and the buoyant density of DVs in CsCl gradients are in the range $1.4\text{--}1.44\text{ g cm}^{-3}$, reported values can be slightly different depending on techniques or buffers used. The major band at $1.39\text{--}1.42\text{ g cm}^{-3}$ contains mostly infectious particles, although a slightly higher density, minor band at $1.45\text{--}1.47\text{ g cm}^{-3}$ is also infectious. Those banding from 1.31 to 1.37 g cm^{-3} are empty or contain incomplete genomes (defective particles). The sedimentation coefficient of a DV is about 110 S. The virion contains 25% DNA and 75% protein and a low percentage of polyamines, such as spermidine.

Purification of DVs includes 3 steps: extraction of virus from infected tissues, followed by virus concentration of viruses and final purification. Virus-containing tissues are lysed by several freeze-thaw cycles and by homogenization in a low ionic strength pH 6–7 buffer. Reducing agents like phenylthiourea, 20 mM sodium ascorbate and EDTA are added to reduce melanisation. Final steps include differential and isopycnic centrifugation.

Structural Features of Virions

The metastable capsid is an essential part of the infectious virion and has multiple functions. These include the protection and isolation of the viral nucleic acid from its environment, the delivery of the viral genome to its replication site and interaction with the host environment while executing the previous two functions. Like their vertebrate-infecting counterparts, densoviruses, possess non-enveloped capsids of 21–25 nm in diameter, adopting a $T = 1$ icosahedral symmetry. The capsid is comprised of 60 monomers, of which an asymmetric unit interacts with the others at a twofold, threefold and fivefold symmetry axes when incorporated into the viral particle.

The structural protein encoding ORF, also known as *cap* can express up to four different VPs of varying lengths, which all share a common C-terminal region. Some densoviruses may possess a split VP gene, which requires alternative splicing in order to be expressed (detailed later). In the case of penstyldensoviruses only one VP of 37 kDa gets expressed, deeming each of the 60 subunits to be identical. This implies that each monomer can execute the same function throughout the viral life cycle of PstDV. Nevertheless, generally, the smallest VP comprising the common C-terminal region, is expressed at a higher level and is therefore considered the major VP. The larger, less abundant VPs are N-terminal extended variants of the major VP, which contain multiple domains and motifs important in the viral life cycle such as the PLA2 domain, a calcium-binding domain, and nuclear localization and export signals. Due to the common C-terminus, the larger VPs are also incorporated into the capsid, albeit at low copy number. In different DVs the size of the major VP varies between 37 and 70 kDa in size.

In contrast to members of *Parvovirinae* for which numerous capsid structures have been determined, only four crystal structures are available for *Densovirinae* viruses along with two low resolution structures that have been determined using cryo-EM (Table 2). Two of the high-resolution structures, for GmDV and AdDV, were determined for DNA packaged (full) infectious virions where only AdDV displayed three ordered pyrimidine bases at the 3-fold symmetry axis luminal surface. This ordering is unexpected given the lack of icosahedral symmetry of the packaged genome. Similarly, to the *Parvovirinae* VP structures, a significant portion of the N-terminal region of the major capsid VP is disordered in DVs. Interestingly, the BmDV1 structure currently represents the only parvovirus VP structure where the last 40C-terminal residues are also disordered.

The parvovirus capsid is comprised of monomers of a single jelly roll core. This highly conserved structural fold is comprised of eight beta strands arranged in two, four-stranded antiparallel beta sheets packed across a hydrophobic interface, with the strands in the sheets traditionally labeled from B to H. When folded, each strand faces opposite its neighboring letter in the alphabetical order, hence a BIDG and CHEF sheet is formed, linked by various numbers of loops, responsible for creating the often surface-exposed variable regions (VRs). For the *Parvoviridae* the BIDG sheet is complemented by an N-terminal fifth strand, designated βA .

In the GmDV VP structure, which is the prototype for the *Densovirinae*, the EF and GH loops are further divided into five and four sub-loops, respectively (Fig. 2). While the GH loop is the longest and forms most of the surface features, its length is significantly shorter compared to the corresponding loop in the *Parvovirinae* members at 97 aa compared to 226 aa in canine parvovirus. As for the *Parvovirinae*, the GH loop is the most variable among ambidensoviruses. At the twofold symmetry axis, all parvoviruses harbor an alpha helix (αA), although densoviruses also contain a second α -helix within the EF loop. PstDV also possesses a third helix in the CD loop and displays significantly shorter EF and GH loops than any of the known densoviral capsid structures (Fig. 2).

Table 2 Densoviral capsid structures resolved to date

Virus	Empty/Full	Structure determination method	Resolution in Å	PDB-ID	Ordered residues included in the structure of total residue number (major capsid protein)
AdDV	Full	X-Ray Crystallography	3.5	4MGU	23–418 of 418 (VP4)
GmDV	Full	X-Ray Crystallography	3.6	1DNV	22–437 of 437 (VP4)
JcDV	Empty	Cryo-EM	8.7	N/A	N/A
AalDV2	Full	Cryo-EM	15.6	N/A	N/A
BmDV1	Empty	X-Ray Crystallography	3.1	3POS	43–454 of 494 (VP3)
PstDV	Empty	X-Ray Crystallography	2.5	3N7X	31–329 of 329 (VP1)

Fig. 2 Densovirus VP structure. (A) Cartoon ribbon diagrams of the ordered common VP structures of *Galleria mellonella* densovirus (GmDV) (top), and *Acheta domestica* densovirus (AdDV), *Bombyx mori* densovirus (BmDV1), and *Penaeus stylirostris* densovirus (PstDV) (bottom). The first ordered N-terminal residue and last C-terminal residue are labeled. The conserved β -core and α A helix are colored in black and labeled in GmDV. Loops and subloops within the major loops are labeled by the major loop name and a number, given according to their order in GmDV. The approximate fivefold symmetry axis is marked by a pentagon, the threefold by a triangle, and the twofold by an ellipsoid. (B) The GmDV VP structure (*Ambidensovirus*, proposed *Protoambidensovirus*) superimposed on the VPs of AdDV (left), BmDV1 (middle), PstDV (right). Diversity on the surface loops are evident.

An important and differentiating feature of the densoviral VP is the domain swapping confirmation observed at their N-terminus (Fig. 3). The densoviral β A strand is a direct extension of the β B strand and it interacts via either hydrogen bonds, metal ions, or hydrophobic interactions with the twofold-related neighboring monomer instead of the β B strand of the very same subunit, as happens in the *Parvovirinae* capsid structures (Fig. 3). Thus, the luminal β BIDG sheet of the jelly roll core is still extended into a β ABIDG sheet as in the *Parvovirinae* and the first observed N-terminal residue is also in a position underneath the 5-fold axis, but in this case, that of the neighboring VP subunit. This swapped confirmation is hypothesized to provide extra stability. The PstDV VP monomer, however, despite displaying the domain-swapped confirmation, is incapable of providing this assessed structural stability.

The overall capsid morphology of DVs can be divided into two types: The larger capsids with diameters of ~ 235 to ~ 260 Å in the depressions and protrusions, respectively, while the smaller capsids measure 215–250 Å, being the smallest capsids so far described for the *Parvoviridae* (Fig. 4). For the former, including GmDV, AdDV, and BmDV1, the capsid surface is smooth with small spike-like protrusions surrounding the 5-fold axes. In GmDV the spikes, formed by the EF4 sub-loop, appear to be smaller compared to BmDV1 and AdDV, due to the protruding GH2 sub-loop filling up the depression surrounding them. In GmDV, a smaller second protrusion is formed by the BC loop. The twofold axes are covered by a depression. In the second group, containing PstDV and AalDV2, there are prominent protrusions surrounding the 5-fold axis, forming two rim-like concentric circles. The 2- and 3-fold symmetry axes have depressions (Fig. 4).

Fig. 3 Multimeric interactions of densoviral and parvoviral VPs. (A) Ribbon diagrams of the interactions between βA and βB at the twofold symmetry axis of *Galleria mellonella* densovirus (GmDV) and canine parvovirus (CPV). The eight-stranded core, with the additional βA , which performs the domain swapping, are colored. (B) Interaction of three threefold-symmetrical VPs for GmDV and CPV are shown. The triangle indicates the threefold axis and the pentagon the fivefold axis. Note the open annulus-like structure at the threefold axis of the densovirus, compared to the more closed arrangement in the vertebrate parvoviruses.

The 5-fold symmetry axis of the DV capsids, like the *Parvovirinae* ones, contains a channel, with a direct opening to the surface. The inner wall of the channel is lined by large hydrophobic residues in all four structures, proposed to provide an interacting surface to a glycine-rich stretch of residues when the N-terminus is externalized during endosomal escape. The densoviral threefold axis, however, is radically different from that of the *Parvovirinae*, occupied by an additional opening besides the fivefold pore instead of the protrusions observed in the *Parvovirinae* (Fig. 4). The opening can be small, formed by the GH loops, which do not even interdigitate between neighboring monomers (PstDV1 of genus *Penstylhamaparvovirus*) or can be occupied by a β -annulus-like structure (subfamily *Densovirinae*). The latter is comparable to the threefold axis of (+) ssRNA viruses, such as Tomato Stunt Mosaic Virus of *Tomoviridae* and Southern Bean Mosaic Virus of *Solemoviridae*. The annulus is formed by charged and flexible residues, with a ~ 10 -Å wide opening in GmDV. This opening is the least pronounced in BmDV1.

Biophysical Features and Functions Associated With the Densovirus Capsid

Compared to members of the *Parvovirinae*, little is known about the functions of densovirus VPs and the available information is based on studies of mostly lepidopteran ambidensovirus. By comparing the VP4 major capsid proteins of two closely related lepidopteran ambidensovirus, GmDV and JcDV, eight variable, exposed regions were identified, located in the vicinity of the fivefold and threefold symmetry axes. Mutating the GH-loop-associated residues in JcDV to their counterpart in GmDV resulted in a decrease of the ability to cross the host midgut epithelium and a reduction of JcDV virulence if introduced through the natural, gastrointestinal pathway. When infecting *Spodoptera frugiperda* hosts *ex vivo*, the mutated virus became mis-targeted and accumulated in subcellular compartments of midgut epithelial cells instead of reaching their target receptors in the basal tight junctions.

Recently, the *Helicoverpa armigera* densovirus 2 (HaDV2) VPs were shown to enhance the structural promoter activity by 35-fold compared to the activation by NS. This suggests that the densoviral capsid proteins may have a non-structural function besides the expected structural ones.

The biophysical properties to date have been investigated only in case of AdDV. Heating of infectious AdDV particles to 70°C resulted in increased PLA2 activity accompanied by genome ejection while capsids remained intact when checked by negative

Fig. 4 Densoviral capsid structures. The capsid surface images show the high resolution structures of *Galleria mellonella* densovirus (GmDV), *Acheta domestica* densovirus (AdDV), *Bombyx mori* densovirus BmDV1 and *Penaeus stylirostris* densovirus PstDV, in comparison with the structure of two vertebrate-infecting parvoviruses, namely adeno-associated virus 2 (AAV2) (Dependoparvovirus) and canine parvovirus (CPV) (Protoparvovirus). The resolution of the structures is provided in parenthesis. The scale bar shows the color code of the radial distance from the capsid center. An icosahedral symmetry diagram indicating the positions of the visible symmetry axes in the capsid images is also shown. The cryo electron microscopy-obtained structures (in gray) of lower resolution are shown for *Aedes albopictus* densovirus 2 (AalDV) and *Junonia coenia* densovirus (JcDV) at the bottom right hand side.

stained EM. Structural studies of these emptied particles, however, did not display increased electron density in the fivefold channels, associated with the VP N-terminal externalization required to expose the PLA2.

Our discovery of PLA2 in capsids of most vertebrate and invertebrate parvoviruses shed light on how the densovirus enters the cell and later escapes the endosome or lysosome. During clathrin-mediated endocytosis the PLA2-containing region of VP1u is externalized through the channel at the 5-fold axis which then enables the virion to breach the endosomal membrane. Almost all parvoviruses contain a calcium-binding loop (GPGN) and the active site (DxxAxxHDxxY) required for PLA2 activity in the N-terminus of the largest minor capsid protein. Brevidensoviruses, penstylidenosoviruses and hepandenosoviruses (subfamily *Hamaparvovirinae*) lack this enzymatic activity and enter probably by direct membrane fusion/penetration reactions at the plasma membrane and might have evolved other, yet unexplored, mechanisms to breach the endosomal membrane.

Densovirus Genome Structure and Replication

As a general rule, capsids of monosense DVs package primarily the “–” DNA strand (complementary to mRNA) while the ambisense DVs package both the “+” and the “–” strands in separate particles. There is a great variety in the organization of genome structures, such as size of DV genomes and genome termini, imperfect palindromic sequences at each extremity able to fold into duplex telomeric structures designated hairpins.

The structural similarities of DV and vertebrate parvovirus genomes suggest common strategies in the replication of their DNA by a single-strand displacement by a DNA polymerase and encapsidation by helicase hexamers into the channel at the 5-fold axis of the preformed capsids. The self-priming hairpin at the 3′ end of the genome serves as primers for complementary strand synthesis according to the rolling-hairpin replication model to generate concatemeric intermediate chain resolved in monomers by the nicking activity of Rep. Based on their viral replication model, the 5′ and 3′ terminal hairpins of all DVs with inverted terminal repeats, including terminal hairpins (ITRs), can exist in either of two orientations termed “flip” and its reverse-complement “flop” orientation. The significant differences in size and structure of palindromic 5′- and 3′-terminal sequences within the different genera of DVs might reflect their dependence on specific cellular factors necessary for the replication of their genome or promote their encapsidation. Ambisense DVs have ITRs whereas monosense genomes can have unique terminal hairpins (e.g., brevidensoviruses) or ITRs (e.g., iteradenosoviruses). An N-terminal HuHuuu amino acid motif (u-bulky hydrophobic residue), with one or two other motifs, was identified in the Rep protein (HUH endonuclease superfamily) that is conserved in two vast classes of proteins, one of which is involved in initiation and termination of rolling-circle DNA replication, or RCR (Rep proteins), and the other in mobilization (conjugal transfer) of plasmid DNA (Mob proteins). One of the two additional conserved motifs is located upstream and the other downstream with a conserved Tyr residue. The major role of these HUH endonucleases is processing a range of mobile genetic elements by catalyzing cleavage and rejoining of single-stranded DNA using an active-site Tyr residue to

make a transient 5'-phosphotyrosine bond with the DNA substrate, such as in rolling-circle replication, in various types of transposition and in intron homing. HUH enzyme activities require a divalent metal ion, coordination which is provided by the HUH motif, to facilitate cleavage by locating and polarizing the scissile phosphodiester bond.

During DV replication the 3' hairpin' provides a free 3'-OH group from which leading-strand synthesis can be initiated using host cell enzymes. The replication of this 3' hairpin is thus incomplete and requires a site-specific nick to generate a second 3'-OH at a specific site (the terminal resolution site, *trs*) in the hairpin so that the complementary strand can be extended to completion. Both terminal hairpins on the two strands can then thus be refolded while the hairpins at the two ends are separated by a duplex.

Rep proteins also contain a C-terminal superfamily 3 (SF3) hexameric 3'-5' helicase domain. RCR uses this 3'-5' helicase activity acting on the template strand to facilitate DNA unwinding at the replication fork. The crystal structure of an SF3 DNA helicase, Rep40, from adeno-associated virus 2 (AAV2) delineates the expected Walker A and B motifs, but also reveals an unexpected "arginine finger" that directly implies the requirement of Rep40 oligomerization for ATP hydrolysis and helicase activity. The peptide linker between the HUH endonuclease and the SF3 helicase domains has a critical role in helicase oligomerization.

Expression Strategies

The expression strategies among the DVs differ considerably (Figs. 5 and 6). The promoters of the *rep* and *cap* cassettes of the ambisense DV genomes tend, at least partially, to be in the ITRs. In addition to unspliced transcripts, splicing and leaky scanning, and even overlapping promoters/ORFs (brevidensovirus), are used to produce a large array of proteins from a compact genome. For ambisense DVs, it is striking that an overlapping 3' untranslated region (UTR) exists, which is shared by both the NS and the VP transcripts.

In GmDV two types of transcription strategies have been described. The transcription and translation map of GmDV (Fig. 5(a)) is a model for closely related densovirus (JcDV, MLDV, PiDV, DsDV, HaDV1, etc) from butterflies. Analogous to vertebrate parvoviruses, the NS gene cassette is to the left and reading from left to right. The VP-encoding cassette, however, is positioned on the complementary strand and is read from right to left. Both expression cassettes are driven by promoters positioned in the ITRs. The relative amounts of the various NS products depend on (1) the strength of the splicing signal and (2) the relative strength of the NS1 and NS2 initiation codons. The relative amounts of VP products depend on the leakiness of the scanning ribosomes and does not involve splicing.

CpDV on the other hand, and though sharing the leaky scanning VP cassette with the lepidopteran ambidensovirus, has evolved a remarkably complex NS expression cassette. The NS-1, NS-2, and NS-3 in the 5' half of one strand are organized into five open reading frames (ORFs) due to the split of both NS-1 and NS-2 into two ORFs. The ORF encoding capsid proteins are positioned in the 5' half of the complementary strand. The expression of NS proteins is controlled by two promoters, P7 and P17, driving the transcription of a 2.4-kb mRNA encoding NS-3 and of a 1.8-kb mRNA encoding NS-1 and NS-2, respectively. The two NS mRNA species have a small 53-nt intron in the middle of the sequence.

The NS expression strategy of AdDV (Fig. 5(b)) is rather like that of GmDV. However, different combinations of splicing donor and acceptor sites result in different N-terminal sequences unlike the truncated sequences as for other parvoviruses. The intron in the NS mRNA occurs in about half of the NS transcripts. Ia, Ib, and II are introns that occur in alternative VP transcripts. NS transcripts start at nt 192 and yield NS3. However, a fraction of these transcripts is spliced just upstream of this start codon (intron), leading to translation of NS1 from 856-AUG, with a poor initiation environment, and, through leaky scanning, of NS2 from 875-AUG. Like the case for all densovirus, the 3' ends of AdDV NS and VP transcripts overlap in the middle of the genome at a 3' UTR sequence, a shared trait by all ambisense DVs to date. VP transcripts are initiated at nt 5235, and VP1 initiation is at nt 5230. The short 5'-UTR predicts an inefficient initiation (leaky scanning) and could be responsible for production of a nested set of N-terminally extended viral proteins. However, removal of either of the two alternative introns in ORF-B (Ia or Ib) did not connect the exons in ORF-B and ORF-A in frame, so only nonstructural proteins could be produced from nt 5230 and VP2 could be produced directly from the first AUG in ORF-A when this splicing occurred. An alternative intron II, which is mutually exclusive with introns Ia and Ib since it removes the ORF-B splice acceptor, connects ORF-B and ORF-A in frame so that VP1 can be produced from nt 5230 (Fig. 5(b)).

The NS expression strategy of the ambisense pefuambidensovirus, PfDV, is the same as for GmDV. Structural analysis of cDNAs complementary to mRNAs from the region coding for structural proteins suggested alternative splicing and polyadenylation as a means for generation of the structural proteins of PfDV.

The NS cassette of the ambisense blattambidensovirus, BgDV1, has an extra NS product (through an extra splice variant, identical to last 273 codons of NS1 (Fig. 5(c))). Alternative splicing in the VP transcript yields a VP2 product with a unique N terminus as for AdDV (Fig. 5(b)).

Although their transcription strategy has not been resolved yet, in some cases, uninterrupted potential ORFs corresponding to non-structural viral proteins or capsid proteins of *Myzus persicae* densovirus (MpDV) and *Dysaphis plantaginea* densovirus (DpIDV), both ambisense hemiambidensovirus, were found within EVEs identified in the aphid genome. Little is known about the expression strategy of the *Aquambidensovirus* genus members. The predicted expression of the SSaDV contig in sea stars is represented in Fig. 5(d).

The phenomenon of possessing a VP expression cassette comprised of two ORFs, united by alternative splicing, appears at four separate DV lineages (e.g., Figs. 5(b) and (c)). The variation in donor- and acceptor site sequence and position as well as in the number of spliced transcripts suggests that this strategy has evolved independently at multiple times during ambisense DV evolution.

b. Scindoambidensovirus (AdDV; GenBank accession no. HQ827781)

c. Blattambidensovirus (BgDV; GenBank accession no. AY189948)

d. Aquambidensovirus (SSaDV; GenBank accession no. PRJNA253121)

Fig. 5 Transcription strategies of ambisense densoviruses. Panels (a, b, c, d) display representatives of four ambisense densoviral genera, according to the new taxonomy classification of subfamily *Densovirinae*. The thick line in the middle represents the coding genome, while genome termini are drawn in thinner lines. The fine lines indicate the starts, ends and intron positions on the mRNAs and promoters at the 5' ends are indicated by small arrows according to the direction of the transcription they drive. Genes and proteins are shown as colored boxes. Thick, bent arrows indicate the leaky scanning translation sites.

a. *Bombyx mori* densovirus 1 (BmDV1; GenBank accession AY033435.1)b. *Aedes albopictus* densovirus 1 (AalDV; GenBank accession no. AY095351)c. *Penaeus stylirostris* penstyldenovirus 1 (PstDV; GenBank accession no. AF273215)d. *Penaeus monodon* hepadenovirus 1 (PmoHDV1; GenBank accession no. NC_007218.1)

Fig. 6 Transcription strategies of monosense densoviruses. Panels (a, b, c, d) display representatives of four monosense genera, according to the proposed new taxonomy of family *Parvoviridae*, classifying *Iteradensovirus* to the original subfamily *Densovirinae*, whereas the remaining three genera are all members of *Hamaparvovirinae*. The thick line in the middle represents the coding genome, while genome termini are drawn in thinner lines. The fine lines indicate the starts, ends and intron positions on the mRNAs and promoters are indicated by small arrows according to the direction of the transcription they drive. Genes and proteins are shown as colored boxes. Thick, bent arrows indicate the leaky scanning translation sites.

As for monosense DVs, the transcription maps and expression of the iteradensoviruses do not show great variety (Fig. 6(a)). The two nonstructural (NS) genes are expressed by overlapping promoters with alternate transcription starts at either side of the NS1 start codon. Leaky scanning yields 4 VP products of which VP1 has PLA2 activity. So far, BmDV1 is the only iteradensovirus with a tandem repeat of 45 nts in the intergenic region.

As for the iteraviruses, brevidensoviruses do not need mRNA splicing since they possess two overlapping P7/7.4 NS promoters (monocytic) located closely to the alternate transcription initiation sites, positioned at either side of the NS1 initiation codon (Fig. 6(b)). Their genomes harbor only one polyadenylation signal, at which both the NS and VP transcript populations co-terminate. VPs are expressed by leaky scanning from only one transcript.

In the penstylidenoviruses (**Fig. 6(c)**) NS1 and NS2 have separate promoters (P2 and P12; Pham, 2014) for NS1 and NS2 where the location of P12 overlaps the intron of NS1, possibly through sequence and motif constraints. The absence of hairpins in the telomeres (Direct Repeats, DR) questions whether PstDV is an authentic parvovirus.

Little is known about the transcription strategy of *Penaeus monodon* hepadensovirus. It has been reported to have a unique expression strategy (**Fig. 6(d)**). Whereas in other densoviruses the initiation codon of NS2 is downstream of that of NS1, the *ns2* gene is located upstream of NS1. The ORF of VP is exceptionally large compared to the protein observed in SDS-PAGE (92 kD vs 57 kD).

Conclusions

Advances in viral metagenomic approaches in recent years have revolutionized the discovery of novel viruses (EVEs and exogenous viruses) from a high diversity of invertebrate hosts. This resulted in suggestions for a significant overhaul of the classification and taxonomy of ambisense densoviruses and the addition of an ancient lineage of highly divergent parvoviruses (*Hamaparvovirinae* subfamily) that infect an exceptionally broad range of vertebrate and invertebrate hosts. For instance, chapparvoviruses found in fish are more closely related to those from invertebrates than they are to those of amniote vertebrates, suggesting parvoviruses to have evolved to infect vertebrates on at least two independent occasions. Currently, host species susceptible to DVs and/or possessing EVEs of suspected DV origin encompass the basal animal phylum Cnidaria as well as both proto- and deuterostome animals. The future directions of DV research must assess and cope with this enormous diversity; a product of parvovirus evolution may flank a 500-million-year-long interval.

Glossary

Encapsulation Encapsulation is a cellular immune response used against pathogens that are too large to be phagocytosed. This response is employed by insect larvae in response to parasitism by wasp parasitoid eggs for example. Encapsulation involves the aggregation of insect immune cells (hemocytes) around the invading body.

Hemocyte The insect blood cells.

Koinobiont parasitoid A parasitoid whose host continues to develop after parasitization.

Melanization In insect immunity, melanization is an immune effector mechanism involved in the killing of pathogens and the eggs of parasitoid wasps. Melanization involves a series of reactions such as the conversion of tyrosine to melanin precursors and the cross-linking of proteins to form a layer of melanin that surrounds and

sequesters an invading body. The death of the parasitoid egg presumably occurs either by oxidative damage or by starvation.

Oviposition Act of laying an egg or eggs.

Parasitoid wasp A wasp the adult stage of which is free-living and whose immature stages feed and develop within or on the bodies of other organisms (usually an insect) that will eventually be killed.

Rep/Helicase A single-stranded DNA-dependent ATPase involved in DNA replication.

Virulence genes Genes responsible for the biological alterations observed in the organism where they are expressed. This term is borrowed from bacterial pathogens that use “virulence factors” to establish on or within a host and enhance their potential to cause disease.

Classification (Compact)

Polydnaviruses (PDVs) are enveloped large DNA viruses with a segmented double-stranded DNA (dsDNA) genome. All PDVs are mutualistically associated with parasitic wasps (also named parasitoids) of lepidopteran larvae.

The Polydnaviridae family was proposed by Don Stoltz in 1984 and recognized by the ICTV in 1991. PDV are divided into two genera, *Bracovirus*, for PDVs associated with wasp subfamilies of the family *Braconidae*, and the *Ichnovirus* for those associated with wasp subfamilies of the family *Ichneumonidae*. BVs are found in wasps from the “microgastroid complex”, a monophyletic assemblage of ~ 50,000 species belonging to six braconid subfamilies. IVs are presently described in two ichneumonid subfamilies, the Campopleginae and the Banchinae, and they are estimated to be associated with at least 14,000 species of wasps.

Life Cycle of PDVs

Among dsDNA viruses, PDVs are the only ones known to be mutualistically associated with multicellular organisms, parasitoid wasps. These insects are characterized by a free-living adult stage and parasitic immature stages. Their host, usually an insect, dies at the end of parasitoid development. Parasitoid wasps associated with PDVs are all koinobiont endoparasites of lepidopteran larvae, i.e. female wasps lay eggs in the body of a host caterpillar, which continues to develop as the parasitoid's offspring matures.

Fig. 1 Life cycle of a parasitoid wasp associated with a polydnavirus. Virus particles are produced in the wasp female ovaries during the pupal and adult stages. Production occurs exclusively in a specialized tissue, the calyx. The produced virus particles are released in the oviducts, and then injected in the parasitoid insect host, a caterpillar, when the female wasp lay its egg(s). Once in the caterpillar, polydnavirus particles infect all the tissues of the insect, viral DNAs reach the nuclei and the genes encoded by the packaged polydnavirus genome are expressed. Successful development of the wasp progeny depends on the expression of these viral genes, which lead to physiological alterations in the caterpillar that are beneficial for the wasp (inhibition of the caterpillar host immune response, modulation of its development, etc.). Once the parasitoid larva (or larvae) ends its development, the mature parasitoid larva egresses from the caterpillar, which dies. The parasitoid then spins a cocoon within which pupation takes place, leading to emergence of a new adult wasp.

BVs and IVs share a common life cycle. They both persist in all cells of the wasp as integrated proviruses. Consequently, PDVs are transmitted vertically through the germline of wasps. During the pupal and adult stage, PDVs replicate in the nuclei of specialized ovarian cells, in a region named calyx (**Fig. 1**). Many virions are produced by calyx cells. BVs are released by lysis of the replicative cells whereas IVs are released by budding. Virions are then stored in the lumen of the oviducts to be injected in the parasitoid host upon oviposition by the female wasp.

PDVs rapidly infect host cells, but no viral replication occurs in the parasitized insect. Infection of the parasitoid host tissues is followed by expression of viral genes on which the survival of wasp offspring depends. Indeed expression of PDV genes disables host immune responses and alters host development and metabolism.

Virion Structure

The virions of BVs and IVs are morphologically and structurally distinct (**Fig. 2**).

BV virions resemble some non-occluded baculoviruses. They have cylindrical, often tailed nucleocapsids surrounded by a single envelope, formed in the nucleus of calyx cells. BV virions contain one or several nucleocapsids. BV nucleocapsids each contain a single DNA molecule. The capsids can vary in length from 30 to 80 nm (excluding tails), with a width around 50 nm.

Fig. 2 Morphology of polydnavirus particles: differences between *Bracoviruses* (upper panel) and *Ichnoviruses* (lower panel). Both bracoviruses and ichnoviruses are produced in a specialized region of the female wasp ovaries, named the calyx; on the left, views of dissected ovaries of parasitoid wasps indicating localization of the calyx. In the center, the upper panel shows bracovirus virions in the oviduct lumen of a braconid female wasp observed by transmission electron microscopy (TEM); the lower panel shows on the left ichnovirus subvirions assembled in the nucleus of a calyx cell, and on the right mature virions present in the oviduct lumen of an ichneumonid female wasp. NC, nucleocapsid; env., envelope; VS, virogenic stroma; iE, inner envelope; oE, outer envelope. Scale bar: 200 nm. Pictures by M. Frayssinet (ovaries) and M. Ravallec (TEM), DGIMI, INRA. On the right of the figure, schematic representations of bracovirus and ichnovirus virions. For bracoviruses, a virion containing multiple nucleocapsids is represented.

IVs have lenticular nucleocapsids surrounded by two-unit membranes. The inner envelope is formed in the nucleus of calyx cells and often presents a “hook-like” structure (or tail) of variable length. The outer envelope originates from the plasma membrane and is acquired during virion budding. Nucleocapsids are uniform in size, they measure more than 300 nm in length and approximately 80–90 nm in diameter. Virions from campoplegine wasps contain a single nucleocapsid, whereas virions of banchine wasps may have multiple nucleocapsids. Note that the virions described in the campoplegine *Bathyplectes* spp. enclose multiple punctiform nucleocapsids. There is no data presently on the number of circular DNA molecules contained in IV nucleocapsids.

Morphogenesis of PDV Particles

PDVs replicate in the nuclei of calyx cells. Both BV and IV nucleocapsids are assembled in virogenic stroma and acquire an envelope in the nucleus (Fig. 3). The origin of the nuclear envelope, and whether it has the same origin in BVs and IVs, remain unknown. BV morphogenesis has been extensively followed for *Chelonus inanitus* BV. During the first steps of replication, virions are assembled and progressively fill the nucleus; “mature” calyx cells, located basally near the oviducts, undergo successive lysis of the nuclear envelope, then of the plasma membrane, leading to the release of the mature virions in the oviduct lumen. On the other hand, the production of IV particles relies on another process. Enveloped subvirions formed in the nucleus exit the later by budding through the nuclear envelope. They finally access the oviduct lumen by budding through the apical plasma membrane.

The PDV Packaged Genome

The genome packaged into PDV virions consist in several multiple circular, double-stranded DNAs that are non-equimolar in abundance. The number and size of DNA segments vary depending on the species (Table 1). BV genomes usually have from 15 to 30 DNA segments ranging in size from 2 to 50 kb, with estimated genome sizes from 125 kb to almost 600 kb. IV genomes consist in 20 to 50 DNA segments, ranging in size from 2 to 28 kb, and estimated genome sizes around 250 kb. The genomes of IV associated with banchine wasps have slightly larger genomes and display a higher degree of genome segmentation compared to campoplegine IVs.

Fig. 3 Schematic representation of the different steps of Bracovirus and Ichnovirus morphogenesis in the wasp calyx cells. On the left, a schematic representation of the wasp ovary indicates the position of the calyx (in red) in braconids and ichneumonids. Bracovirus (BV) and ichnovirus (IV) virions are assembled in the nucleus of the calyx cells, in specific regions named virogenic stroma. For BVs, along with nucleocapsid production, two-unit membrane envelopes appear in the nucleus. Nucleocapsids are enveloped to form mature virions that accumulate in the nucleus. Release of virions occurs by disintegration first of the nuclear and then of the plasma membrane. For IV, assembly of sub-virions (i.e. nucleocapsids surrounded by a single two-unit membrane envelope) takes place in the vicinity of the virogenic stroma. Sub-virions then migrate towards the nuclear envelope where they bud to the calyx cell cytoplasm. Sub-virions then reach the plasma membrane and bud through it to finally reach the calyx lumen where they accumulate as mature virions surrounded by two envelopes. In contrast to what occurs in BV-producing cells, IV-producing cells do not undergo cell lysis; each calyx cell can a priori produce virus particles during the entire female adult life.

Sequencing of PDV packaged genomes revealed they generally encode more than 100 predicted genes. The genes encoded by PDV genomes differ in nature in BVs and campoplegine IVs (Table 2); interestingly banchine IVs share gene families with BV (PTPs and viral ankyrins). The most represented gene family in BVs, in terms of number of genes, are the PTPs, with generally more than 30 genes identified in the sequenced genomes. For IVs, the most represented gene family is the repeat-element genes, with also often more than 20 members identified in IV genomes; they have no similarities with known genes, but all contain a 540 nt motif that make them related. Both BV and IV genomes possess genes encoding proteins harboring ankyrin domains (viral ankyrins);

Table 2 Gene families identified in polydnavirus genomes. Are listed the main viral gene families encoded by bracoviruses (BV, on the left) and by ichnoviruses (IV) associated with campoplegine wasps (on the right). Conserved families are those encountered in all sequenced genomes for a polydnavirus genera; for BVs are also indicated gene families found in several species but not all; Specific gene families are examples of genes found in a single polydnavirus species, knowing that only a few polydnavirus packaged genomes have been sequenced so far

Gene families conserved in all sequenced BVs (and in IVs associated with banchine wasps)	Gene families conserved in all sequenced IVs associated with campoplegine wasps
Protein tyrosine phosphatase (PTP)	Repeat-element gene
Viral ankyrin	Cys-motif protein
Gene families conserved in some BVs	Viral ankyrin
Cystatin	Viral innexin
CrV – 1 like protein	Polar-residue rich protein (PRRP)
Lectin-like	N-gene
Specific gene families	Specific gene families
Egf-motif (MdBV)	Glycine-proline rich (HdIV)

MdBV, *Microplitis demolitor*; Bracovirus; HdIV, *Hyposoter didymator* Ichnovirus.

however whether BV and IV viral ankyrins are related or derive from independent acquisitions in the two wasp lineages has not yet been demonstrated.

As a rule, based on analysis of all the PDVs sequenced, no typical virus replication genes have been identified in PDV packaged genomes. Nonetheless a helicase gene was identified in *Cotesia vestalis* BV; however, further work revealed that it was actually a Rep/Helicase from an intact Helitron transposable element inserted into a virus segment.

Function of the Genes Encoded by PDV Packaged Genome

The packaged genome is transferred to the host of the parasitoid upon parasitism, where the genes are for the most part expressed. These genes are thus considered as “virulence” genes, responsible for the physiological alterations observed in the parasitized insect and on which rely successful development of the wasp progeny. A number of these genes, such as PTPs, viral ankyrins, cystatins, and viral innexins have similarities with eukaryotic genes. The hypothesis is that these genes have an insect, probably a wasp, origin rather than a viral origin.

PDVs have early been shown to be necessary for successful development of the wasp. They are indeed involved in immune suppression (e.g., changes in hemocyte composition, cellular spreading, encapsulation and melanisation) and alterations of development (e.g., modification of growth hormone titers) or metabolism (e.g., changes in levels of total carbohydrates, lipids or proteins) in the parasitized insect. PDV physiological effects have been shown by phenotypic approaches but also indirectly by transcriptomic approaches. However, amongst the hundred genes encoded by PDVs, the physiological roles in parasitism of only a few has been investigated so far (Table 3). This is probably due to the absence of similarity to known functional proteins for the majority of PDV encoded proteins, but also, and most probably the main reason, due to the technical difficulty to study these viruses which are not replicative in the insect where genes are expressed and functional.

Apart from physiological effects, recent studies have amazingly also highlighted ecological roles for PDVs. PDV infection affects protein expression in salivary glands of the parasitized insect; and particularly proteins that act as elicitors of the plant response are affected in terms of abundance. This leads to induction of the plant immune response and emission of volatiles that differ from those induced by a non-infected phytophagous insect, and consequently impact trophic interactions between the plant, the phytophagous insect, its parasitoids and even the hyperparasitoids.

Because PDVs are essential for parasitoid survival, it is expected that these mutualistic viruses impact parasitoid host range. Indeed, PDVs were shown in at least one case to be involved in the specialization of parasitoids to their hosts.

Fate of the PDV Packaged Genome in the Parasitized Insect

Larval development of parasitoid larvae within their lepidoperan hosts last several days, a time period during which PDV continue to be active. Expression of PDV genes is detected early after parasitism and during all the parasitoid development in the parasitized insect. Since PDV particles are non replicative (absence of replication genes), this raises the question of how PDV DNA is maintained in the lepidopteran host of the parasitoid. Early studies in cultured cells showed that portions of PDV segments were capable of integration into the genome of lepidopteran cells. More recently, integration of BV segments in genomic DNA of the host was shown in vivo. Integration into host cells occurs rapidly after infection and in association with a domain termed the “host integration motif” (HIM) (Fig. 4), which was identified in most MdBV genomic DNAs and several CcBV circles. This finding suggests that BV genomic segments integrate into host cells through a shared mechanism. However, no specific host genomic target could be identified, despite the fact that integration was not totally random within the lepidopteran host genome. Nonetheless, this process allows PDV to persist and throughout parasitism.

Table 3 Some examples of polydnavirus (PDV) or PDV genes effect on the physiology of the parasitized caterpillar host. PDV infection affects either the host immune response (Immunity) or its development (Development). For each gene studied, the observed effect is indicated

A consequence of this property of PDVs is occurrence of lateral transfers on lepidoptera genomes. Indeed, insertions of bracovirus sequences are present in the genomes of certain moth and butterfly lineages; the viral genes present in these sequences have been co-opted by lepidopteran species to confer some protection against pathogens.

The Proviral Genome Maintained in the Wasp Genome

PDV sequences persist in all cells of the wasp as integrated proviruses. PDV chromosomal genomes include two functional components, the viral segments encoding the virulence genes and the viral replication genes (Fig. 4). The segmented proviral sequences are amplified, excised and circularized as dsDNA molecules that are packaged into the particles to be delivered to the caterpillar host. On the other side, DNA for the replication genes, which are also amplified, are not encapsidated and remain in the wasp. The latter are expressed specifically in calyx cells during virus replication and encode proteins found, for the majority of them, associated with the virus particles (by proteomic analyses of purified particles); they constitute the viral machinery that produces the PDV particles. These viral machineries derive from the PDV viral ancestor, which differs between BVs and IVs.

Organization of PDV Proviral Segments in the Wasp Genome

Proviral segment organization in the wasp genome differs between BVs and IVs. The first data came from the analysis of genomic clones from two *Glyptapanteles* braconid wasps. It was the first demonstration that BV proviral segments were organized in “macro-loci” containing several segments arranged in tandem array. The organization in macro-loci of BV proviral segments was confirmed by later studies on several *Cotesia* species and *M. demolitor*. The number of macro-loci and the number of segments differ between species, but globally, braconid wasps harbor in their genome a dozen viral loci containing from 18 to a single segment. For *M. demolitor*, availability of the whole genome allowed the demonstration that the eight loci containing MdBV proviral segments were flanked by large distances of wasp genomic DNA, suggesting a wide distribution of the viral loci within the wasp genome. Organization in clusters may facilitate concerted segment DNA amplification during BV replication. Indeed, it was shown that BV segments are amplified within replication units (RU) composed of several segments and including intersegmental sequences that are not encapsidated. The hypothesis suggested by the authors is that the concatemer is first excised and then sub-divided into individual segments. The organization of proviral segments is quite different in ichneumonids. The genome of two campoplegine species *Hyposter didymator* and *Compoletis sonerensis* reveals that IV segments are highly dispersed across the wasp genomes. Therefore the question on how the coordinated amplification of all the viral loci is regulated remains unanswered.

In its linear form, each PDV segment is flanked in its extremities by a direct repeat, named “direct repeat junction” (DRJ). DRJs are the regions where homologous recombination takes place allowing excision of the segment; consequently, a single copy of the DRJ sequence is present in the circular molecule (Fig. 3). In IVs, no consensus sequence has been identified. Conversely, in BVs,

Fig. 4 The different forms of PDV genomes. In the wasp, PDV genome sequences are present as integrated proviruses composed of two components. One component is composed of proviral segments, each of which are flanked by direct repeat junctions (DRJ) (dark blue arrows) and encode virulence genes (blue squares). Homologous recombination at the level of the DRJs allows segment excision and leads to the formation in the calyx cells of double stranded circular DNA molecules. For BVs, amplification of segments within replication units was shown to precede segment excision. The other proviral component corresponds to genes belonging to “BVSPERs” or “IVSPERs” “BV or IV structural proteins encoding regions” (red squares). In the case of BVs, these regions correspond to genes of nudiviral origin, whereas in the case of IVs the genes belong to a yet to be described virus. Expression of these genes in the calyx cells allows production of viral particles and the packaging of the double stranded circular molecules. These non-replicative PDV particles are then injected inside the caterpillar along with wasp eggs upon parasitism. Expression of PDV virulence genes occurs early after parasitism and is in part necessary for successful wasp development. PDV DNA was shown to persist in the genome of cultured lepidopteran cells. In the case of BVs, integration of BV DNA segments into genomic DNA of the host during parasitism was described for molecules containing a 100 bp “Host Integration Motif” (HIM). During integration BV circles are opened within the HIM, a short 40–50 bp sequence of the circle is lost and the remaining HIM sequences flanking this lost sequence become the extremities of the BV sequences integrated in the host DNA, these extremities are named Junction 1 and 2 (J1 and J2) and are represented by dark green lines. The fate of molecules that do not contain HIM sequences awaits investigation. The wasp genome is represented by a gray line. DRJs are represented by dark blue arrows. PDV virulence genes are represented by blue squares, virus-derived genes encoding virion structural proteins are represented by red squares. The lepidopteran genome is represented by an orange line. The HIM is represented by a green square, and J1 and J2 sequences by dark green lines.

DRJs contain a conserved tetramer AGCT, shown to be the site where the segment circularizes. Note that this motif differs from the host integration motif (HIM) mentioned above.

The PDV Viral Machineries

One of the major findings of the last 10 years in the field of PDVs has been the discovery by coupling calyx transcriptome and virus particle proteome analyses, of the virus ancestors and of the virus-derived machineries allowing for the production of PDV particles. Importantly, BVs and IVs do not share a common viral ancestor, they have different evolutionary origins. BVs descend from the integration in the genome of an ancestral wasp of a nudivirus genome, whereas IVs originate from the integration of a still undetermined virus.

Nudiviruses represent a sister-group of baculoviruses, with which they share a set of core-genes. A large proportion of nudiviral structural core genes was found to be maintained in the braconid wasp genome. These nudivirus-like genes potentially (1) code for the different subunits of a DNA-dependent RNA polymerase and the *lef-5* initiation factor involved in transcription; (2) are involved in producing and assembling viral nucleocapsids; (3) code for a set of *per os* infectivity factors (PIFs) that could be involved in infection of host cells; or (4) are constituents of the viral particles (see Table 4). Several lines of evidence suggest that nudivirus-like genes in braconid wasp genomes have retained their ancestral function. First, nudivirus-like gene expression dynamics are consistent with the different steps in virion formation. Secondly, proteomic analysis showed that products corresponding to capsid or envelope components can indeed be present in the BV virions. Finally, RNA-interference experiments in *M. demolitor* showed that the *Lef-4* and *Lef-9* RNA polymerase subunits are necessary for transcription of viral structural genes involved later in the virion cycle. RNA-interference in this model also revealed that *vp39*, *p74*, and *pif-1* are required for virion formation; while *vlf-1* and the integrase display functions required for DNA excision and circularization. Notably, however, none of the braconid genomes sequenced so far possess a DNA polymerase of viral origin, suggesting viral amplification is under the control of wasp DNA polymerases. Half of the nudiviral genes identified within the genome of the braconid wasp *Cotesia congregata* are localized in a 17 kb region referred to as the “nudiviral cluster” whereas the other nudiviral genes are dispersed in the wasp genome. A nudiviral cluster was similarly found in the *M. demolitor* genome displaying a conserved synteny of structural genes with the *Cotesia congregata* nudiviral cluster. This observation shows that these nudiviral clusters have remained stable since divergence 53 MYA between the *C. congregata* and *M. demolitor* species.

Regarding IVs, virus-derived genes encoding virion structural proteins were all found in distinct regions of the genomes of the campoplegine *Hyposoter didymator* and *Camponotus sonorensis*, and of the banchine *Glypta fumiferanae*. These regions were termed “IV

MdBV, *Microplitis demolitor* Bracovirus; CcBV, *Cotesia congregata* Bracovirus; CiBV, *Chelonus inanitus* Bracovirus. +, gene present; –, gene absent; nd, gene not detected to date. Gene names in bold correspond to core genes that are also conserved in baculoviruses.

Structural Proteins Encoding Regions" (IVSPERs). Five IVSPERs ranging in size from 2 to 30 kbp were identified in the *H. didymator* genome, and *C. sonorensis* genomes, and three IVSPERs were also identified in the *G. fumiferanae* genome. So the large majority of the replication genes are clustered in the wasp genome, although both campoplegine wasps genomes also contain one or two isolated genes. IVSPERs of these closely or distantly related species showed clear inter-taxonomic homology detected for several IVSPER genes. The function in particle assembly and trafficking was demonstrated for six *H. didymator* replication genes through RNA-interference experiments, clearly showing that IVSPER genes have classical viral functions.

Concluding Remarks

Polydnaviruses are unusual viruses due to their atypical life cycle and to their genome composed of two functional components. The virus particles are non replicative and merely consist in gene transfer systems allowing delivery of virulence wasp genes to the host of the parasitoid. As a consequence, the virus status of PDVs could be questioned. Nonetheless, via the replication genes that derive from the viral ancestors, PDVs still possess typical virus characteristics, as the endogenous viral elements present in the wasp genomes have clearly retained their ancient viral functions.

Polydnaviruses have a complex life style and they are still wrapped in many mysteries, especially in regard to the field of classical, molecular and evolutionary virology. For example, how these genomes are regulated to produce the viral particles, what are the mechanisms underlying particle assembly, where do the envelopes that form in the nuclei come from, how do these integrated genomes evolve, etc ... so many research questions that future generations will have to answer before the mystery of these unique domesticated viruses becomes somewhat clearer.

Glossary

Alkaline midgut The midgut of the lepidopteran larvae has a pH about 10.5 and contains proteases active at this high pH.

Apoptosis Programmed cell death. Viruses, toxins, etc. induce apoptosis in certain cells.

Ecdysteroids Arthropod hormones responsible for molting and development.

Epithelial cells A layer of cells the form part of the midgut and is permissive to virus infection.

Fusolin It is the main protein of the spindle body. The N-terminus is associated with degradation of the peritrophic membrane and enhances virus access to epithelial cells.

gfp A gene encoding the green fluorescent protein, GFP.

Juvenile hormone A group of hormones that regulate larval growth and prevent metamorphosis.

Lateral bodies Proteinic bodies present in the virion as a single unit on one side of a unilateral concave core in alphaentomopoxviruses or as two units on either side of a cylindrical viral core (beta- and gammaentomopoxviruses).

Malpighian tubules A system for the elimination of metabolic waste as well as regulators of osmolarity.

Peritrophic membrane It is a non-cellular, semi-permeable membrane composed mainly of chitin, which lines the larval midgut. It improves digestion, protects against chemical and mechanical damage and acts as a barrier to pathogenic infections.

Phylogeny It is the evolution of genetically related organisms (here viruses) by studying their gene or protein evolution through comparison of homologous sequences.

Spheroid A proteinic body into which mature virions are embedded. The spheroid also contains an endogenous alkaline protease. It serves as a protective agent as it delivers the virus to the larval midgut.

Spindles A para crystalline body that in some entomopoxviruses become occluded into the spheroid late in the infection cycle.

Tracheoblasts Cells derived from epidermal cells that line the trachea to give rise to the tracheoles.

Introduction

Over the decades, poxviruses have been associated with a most serious smallpox infection caused by two poxviruses, Variola major and Variola minor (Genus *Orthopoxvirus*), which resulted in millions of human deaths before it was eradicated with the last case reported in October 1977. Entomopoxviruses (EPVs) were discovered by C. Vago in 1963 where he noted very close structural similarities to poxviruses of vertebrates. EPVs, however, are distinguished by the synthesis of a spherical-like structure, termed spheroid or occlusion body into which virions are embedded at the end of the viral replication cycle. The spheroid consists mainly of a protein, spheroidin of 110–115 kDa and functions much like the polyhedra of nucleopolyhedroviruses. Spheroids and polyhedra afford the occluded virions a certain amount of protection against inactivating environmental conditions such as desiccation, UV light, heat, etc. but are also the means to deliver the virus to permissive midgut cells in the host insect. To date, EPVs have been isolated from Coleoptera, Orthoptera, Lepidoptera and Diptera and the German cockroach, *Blattella germanica* (Order: Blattodea). As in other poxviruses, EPVs replicate in the cytoplasm, primarily because the virus particle carries a DNA-dependent RNA polymerase to initiate the early stages of gene expression. The virus forms an electron-dense virogenic stroma or viral factories where virions are assembled as spherical immature particles. These virus particles develop into brick-shaped intracellular mature virions (IMVs) that are either released upon cell lysis or acquire a second double membrane from trans-Golgi and bud as external enveloped virions (EEVs). Mature virions become occluded in spheroids late in the infection cycle and remain intracellular until cell lysis. Intracellular particles are highly infectious and, indeed, cells infected with *Amsacta moorei* EPV (AMEV) can cause a systemic infection in the gypsy moth, *Lymantria dispar* by *per os* inoculation. Virus purified from spheroids does not cause a systemic infection in *L. dispar* by *per oral* inoculation as this insect is not its natural host.

Classification

The family *Poxviridae* is divided into two subfamilies, *Chordopoxvirinae*, which encompasses several genera of viruses that infect chordates and *Entomopoxvirinae*, which encompass poxviruses of insects and has been subdivided to contain four genera:

- *Alphaentomopoxvirus* of which the species *Melolontha melolontha entomopoxvirus* is represented by *Melolontha melolontha* EPV (MMEV). Members of this genus infect coleopteran insects (beetles). Virions are 450×250 nm in size and ovoid in shape. They contain a unilateral concave core and a single lateral body. The genome size of these viruses is in the order of 260–370 kb.
- *Betaentomopoxvirus* of which the *Amsacta moorei entomopoxvirus* is the type species. Viruses of this genus infect lepidopteran insects (butterflies and moths). The virions contain a cylindrical core, a “sleeve-shaped” lateral body and are similar in shape to alphaentomopoxviruses (ovoid) but smaller in size (250×350 nm).
- *Deltaentomopoxvirus* of which *Melanoplus sanguinipes entomopoxvirus* is the type species. Members include Orthopteran EPVs such as *Melanoplus sanguinipes entomopoxvirus* ‘O’ (MSEV).
- *Gammaentomopoxvirus* of which the *Chrinomus luridus entomopoxvirus* is the type species. Members of this genus that infect dipteran insects (mosquitoes and true flies) are brick shaped ($320 \times 230 \times 110$ nm) and the virions contain two lateral bodies and a biconcave core.
- Unassigned species in *Entomopoxvirinae*: *Diachasmimorpha entomopoxvirus*

Host range, morphology and virus size are the criteria for the different genera.

Poxviridae and *Iridoviridae* have been grouped as eukaryotic nucleocytoplasmic large DNA viruses (NCLDV) with double-stranded genomes and complete part or all their replication and capsid assembly in the cytoplasm. *Ascoviridae* may also be included in this group. There is a proposed order *Megavirales* to include the above virus families along with *Mimiviridae* and *Phycodnaviridae*.

Virus/Midgut Interactions

Infection starts when larvae ingest plant material contaminated with spheroids that contain occluded virus particles (Fig. 1). Spheroids dissolve in the alkaline environment of the midgut with the aid of an endogenous alkaline protease. Released virions negotiate the peritrophic membrane and attach to permissive epithelial cells. Infection is enhanced in part by a virus-encoded protein termed fusolin which appears to cause significant disruption of the peritrophic membrane. Fusolin is the major protein of spindle-like structure and is occluded into the spheroids of most EPVs (Fig. 2). Some EPVs do not occlude the spindles such as the *Anomala cuprea* EPV (ACEV) and *Pseudaletia separata* EPV (PSEV). Fusolins are conserved at the amino acid level and exhibit significant identity with an apparently unrelated baculovirus (BV) protein, GP37. Both fusolin and GP37 have a 20 amino acid leader sequence that is cleaved post translationally. Interestingly, GP37 forms spindle-like structures in the cytoplasm of certain nucleopolyhedrovirus infected cells (Fig. 3). Fusolin not only enhances the infectivity of EPVs, it also appears to interact functionally with BVs and boosts the infectivity of some nucleopolyhedroviruses (NPVs). The spindle protein, not the spheroid, causes the disintegration of the peritrophic membrane in the silk moth to aid the penetration of greater numbers of NPV virions into microvilli.

A series of deletion ACEV fusolin mutants were constructed, expressed in a BV expression system and assayed for enhancement of BmNPV infectivity. It was observed that the N-terminus of fusolin (aa 1–253) is essential to enhance the infectivity of BmNPV in

Fig. 1 *Choristoneura biennis entomopoxvirus* is occluded within a spheroid. Arrow points to virions maturing within the spheroid.

Fig. 2 Virions and spindles (arrow) occluded within a spheroid.

Fig. 3 GP37 spindles in the cytoplasm of CF70 cells infected with *Choristoneura fumiferana* defective nucleopolyhedrovirus (CfDEFNPV).

the silk moth. Interestingly, that part of the N-terminus is a chitin-binding domain that causes degradation of the peritrophic membrane. Also, essential to fusolin activity and stability in midgut juices is the glycosylation of N191. The carboxy-terminus does not appear to play a role in this function.

As with many other viruses, EPVs induce apoptosis upon infection of certain cells. Most but not all EPVs contain inhibitor of apoptosis genes (*iap*) but their anti-apoptotic properties have not been established. BVs express a virus-encoded protein, P35, that targets cellular caspases to inhibit apoptosis. AMEV encodes P33, which is a functional homolog of the baculovirus P35 protein, which inhibits programmed cell death in certain insect and human cell lines. It is specific for effector but not initiator caspases and mutagenesis of the caspase cleavage site annuls cleavage and subsequent anti-apoptotic activity.

Replication in Larvae

Much like the occlusion bodies of baculoviruses, the function of the spheroid is not only to give the virions a certain amount of protection in the environment but, more importantly to deliver the virus to permissive midgut cells. The spheroid contains an endogenous alkaline protease that aids in dissolution to efficiently release the virions. Initiation of infection starts when the outer envelope protein of the virion attaches and fuses with the plasma membrane allowing entry of the viral core and lateral bodies into the cell cytoplasm. The entry–fusion complex in chordopoxviruses (ChPVs) has been substantially elucidated, primarily in vaccinia

Table 1 Potential EPV genes related to fusion entry complex and orthologs in Fowlpox virus

Predicted Function Structural	Homologs to AMEV	Homologs to MSEV	Homologs of Chordopoxvirus
Myristylated protein (Cop-G9R)	AMEV – 035	MSEV-Tuc – 121	FWPV-Iowa – 127
Myristylated Entry/Cell-cell fusion protein (Cop-A16L)	AMEV – 118	MSEV-Tuc – 090	FWPV-Iowa – 181
Unknown MP (Cop-J5L)	AMEV – 232	MSEV-Tuc – 142	FWPV-Iowa – 136
S-S bond formation pathway protein (Cop-F9L)	AMEV – 243	MSEV-Tuc – 094	FWPV-Iowa – 112
Entry and Cell-Cell Fusion (Cop-A21L)	AMEV – 249	MSEV-Tuc – 209	FWPV-Iowa – 186
IMV MP/Virus entry (Cop-A28L)	AMEV – 186	MSEV-Tuc – 132	FWPV-Iowa – 192
Entry and Cell-Cell Fusion (Cop-H2R)	AMEV – 127	MSEV-Tuc – 060	FWPV-Iowa – 139

**Fig. 4** Viroplasm of CBEV infected cells and maturing budded virions. Intracytoplasmic virus particles are at various stages of maturity. Arrows point to electron-dense virogenic stroma.

virus and the H3 component of the complex is a homolog of the AMEV, *amu248*. **Table 1** delineates AMEV ORFs potentially encoding components of the entry–fusion complex and orthologues in Fowlpoxvirus. Virus replication is exclusively in the cytoplasm of infected cells in electron dense viroplasm or virus factories where immature virion cores are formed. Maturation of the virions in some hosts occurs after occlusion into the spheroids (**Figs. 1 and 2**). Also, extracellular virus may mature following budding from infected cells (**Fig. 4**).

EPVs infect four orders of insects, Lepidoptera, Orthoptera, Diptera and Coleoptera and, while the virus is infective to larvae, an EPV of the European spruce bark beetle, *Ips typographus*, appears to target adult insects only.

The primary larval tissue that supports virus replication is the fat body although other tissues also become infected. *Melanoplus sanguinipes* EPV (MSEV) is more restricted and infects fat tissue and haemocytes. A more comprehensive pathway is seen when AMEV tagged with a *gfp* marker under the control of the very late *spheroidin* promoter is used to infect the gypsy moth, *Lymantria dispar* by the per oral route. Since *gfp* is under the control of the very late *spheroidin* promoter, GFP expression indicates the virus has completed productive replication. The first signs of fluorescence are in the haemocytes that appear to carry the virus to the rest of the larval tissues. Unlike BVs, where the trachea is the conduit to disseminate the virus systemically, AMEV does not appear to infect tracheoblasts (**Fig. 5**) until the very late stages of infection of larva and by that time the virus has spread to all susceptible tissues. The fat tissue however is still the main site that supports virus replication where the virus progressively invades all cells and the tissues become the main site for productive replication (**Fig. 6**). Virus replication also occurs in the silk glands, the hind- and midgut. The malpighian tubules are refractory to infection. At the latter stages of infection, the gypsy moth becomes totally fluorescent with GFP (**Fig. 7**).

Fig. 6 Gypsy moth fat tissue infected by AMEV *gfp*⁺ *sph* at different hours post infection (pi). Reproduced from Perera, S., Zhen, L., Pavlik, L. and Arif B. (2010). Entomopoxviruses. In *Insect Virology* (Edited by: Sassan Asgari and Karyn N. Johnson), pp 83–102. Caister Academic Press, UK.

To date, EPVs have not been used to any extent in the control of agricultural or forest insect pests primarily because the virus takes a long time to kill the insect, usually 4–5 weeks. There has been some correlation observed between the host and the amount of time it takes to kill the larvae. For example, coleopteran EPVs could take up to 37 weeks, and may be temperature dependent. On the other hand, lepidopteran EPVs take about 4 weeks. Apart from general morbidity, symptoms of infected larvae differ from host to host. Larvae of the lepidopteran lesser cornstalk borer, *Elasmopalpus lignosellus* become unresponsive and sluggish just before they die. Their cuticle changes from brown to reddish in color and the hemolymph turns white or light blue. EPV-infected black-soil scarab, *Othnonius batesi* develop a characteristic white-spotted or mottled exterior triggered by the accumulation of infected fat body in the last segment that enclose the rectal sac. Lepidopteran larvae such as the Winter moth, *Operophtera brumata* and the Army cutworm, *Euxoa auxiliaris* become whitish but the Salt marsh caterpillar, *Estigmene acrea* remain dark after infection. Infected larvae of the Eastern spruce budworm, *Choristoneura fumiferana* (CFEV) or the Two-year-cycle budworm, *C. biennis* EV (CBEV) become much larger in size because pupation is either delayed or inhibited until they die. EPVs interfere with metamorphosis by modulating the levels of juvenile hormone (JH) and ecdysteroids in the hemolymph. Larvae treated with JH, appear to undergo similar symptoms. When infected with EPV, many die as larval/pupal or pupal/adult intermediates. It appears that upon infection with an EPV, the level of JH is elevated with a concomitant reduction of the ecdysteroid titer.

Fig. 7 Latter stages of a whole gypsy moth larva infected with AMEV *gfp*⁺ *sph*[−] exhibiting GFP expression due to virus infection.

Table 2 Sequenced entomopoxvirus genomes

Viral Genome	Size in bp	Size of ITR in bp
Anomala Cuprea EPV	245,717	22,978
Amsacta moorei EPV	232,392	9458
Choristoneura biennis EPV	307,691	23,817
Choristoneura rosaceana EPV	282,895	13,406
Adoxophyes honmai EPV	228,750	5617
Mythimna separate EPV	281,182	7347
Melanoplus sanguinipes EPV	236,120	7201

Genomics

Conserved and Shared Genes

Poxvirus genomes share 49 core genes completely conserved among members of *Chordopoxvirinae* and *Entomopoxvirinae*. The conserved genes play roles in key functions such as transcription, DNA replication and virion structural assembly and are considered essential for virus survival and may even reflect a minimum poxvirus genome. At least 90 genes are common to all ChPVs genera including the 49 core genes. While the central region of the genome contains genes required for essential functions, the termini contain genes specific to a particular genus and some are involved in virus/host interactions. Some genes in the termini encode virulence proteins to counteract the host's immune responses.

During the co-evolution of ChPVs with their hosts, the virus acquired genes encoding proteins needed to evade the host's immune responses. A similar process has most likely developed in EPVs and will probably be elucidated as more studies are conducted on the interactions of EPVs with their natural hosts.

Several EPV genes and their homologs in ChPVs have been characterized with respect to their temporal transcription and viral functions. The AMEV protein kinase gene (*amv197*) is expressed early and encodes a protein of 299 amino acids with conserved serine/threonine protein kinases (PK) domains. In a yeast two-hybrid system, this enzyme and another PK encoded by *amv153* interacted specifically with a number of viral proteins including two involved in the fusion entry complex. Interestingly, *amv133* encodes a protein with two types of enzyme activities, an esterase and a protease.

In comparison to ChPV, to date, only seven EPV genomes have been completely sequenced (Table 2). The EPV genomes are distinguished by having a very high A + T content measuring 79%–82%. A characteristic poxvirus genome, including EPVs, comprises a highly conserved central region where genes and ORFs show collinearity flanked by variable terminal regions. In relation to ChPVs, the central region in the EPV genomes have undergone significant gene rearrangements during the evolutionary separation of the two poxvirus subfamilies. Indeed, comparison of gene order and arrangements in the central part of the genomes of AMEV, CREV, CBEV and MSEV (Fig. 8) reveals almost complete collinearity in the first three betaentomopoxvirus genomes. Gene order has been practically totally rearranged in the genome of MSEV thus ascertaining its divergence from the betaentomopoxviruses, as recognized by the ICTV by being classified in the new (2019) *Deltaentomopoxvirus* genus (Fig. 9).

The first EPV genome to be completely sequenced was the 236-kb MSEV genome containing 267 ORFs. In 2000, the sequence of AMEV (232-kb) became available and was assumed to have 294 protein-coding ORFs. The sequences of five other genomes were reported later (Table 2) and, as in other poxviruses, EPV genomes contain inverted terminal repeat regions (ITR) which range from 5.6 kb to about 24 kb in length (Table 2).

Fig. 8 Gene collinearity in the central part of the genomes of AMEV, CREV, CBEV and MSEV.

Fig. 9 Unrooted phylogeny of EPVs based on the protein, spheroidin. Reproduced from Perera, S., Zhen, L., Pavlik, L. and Arif B. (2010). Entomopoxviruses. In *Insect Virology* (Edited by: Sassan Asgari and Karyn N. Johnson), pp 83–102. Caister Academic Press, UK.

The initial prediction of 294 protein-coding ORFs in the genome of AMEV is probably an over estimate and the actual number may be significantly less. Based on purine content and the average aspartate-glutamate-serine composition, a method was described to predict functional ORFs in A + T rich genomes. By this method, 45 of the previously considered ORFs in the AMEV genome are likely to be non-coding and cannot be considered as genes. By using the Z-curve method, two other studies predicted that 38–48 previously annotated AMEV ORFs do not encode proteins. Based on the latter two studies, the AMEV genome encodes 246–256 functional proteins, which is significantly less than the 294 ORFs reported earlier.

Table 3 Poxvirus gene families with orthologs in MMEV and MSEV

Family	AMEV ORF	MSEV ORF
ALI (alanine-leucine-isoleucine motif)		
Subgroup 1	AMV257	MSV024, 026, 196, 204
Subgroup 2	AMV 055, 057, 175, 177	MSV023, 194, 195
Leucine-rich repeats (LRR)	AMVITR01, AMV005, 014, 076,134	MSV008, 009, 010, 011, 013, 014, 015, 016, 018, 186, 227, 228, 239, 240, 241, 253, 254, 255, 257, 260, 261
Methionine-threonine-glycine (MTG)	AMV194, 207, 209	MSV021, 191, 198, 199
Tryptophan (W) repeat	AMV029, 254	MSV027, 029, 034, 197, 205, 252
AMV176	AMV56, 176, 178	
Serine-cystein-glycine (SCG)		MSV062, 214, 215, 216, 217
17K ORF (KilK-N domain-containing proteins)		MSV062, 214, 215, 216, 217

The genome sequence of the EPV infecting the Oriental beetle, *Anomala cuprea* (genus *Alphaentomopoxvirus*) revealed that it is 245,717 bp long, smaller than previously reported and contains the 49 core genes conserved in poxviruses. Because only one *Alphaentomopoxvirus* genome has been sequenced and five from the genus *Betaentomopoxvirus*, it is a too early to make generalized conclusion as to the major differences between viruses from the two genera. However, some differences are worth mentioning. For example, ACEV does not have a homolog to the apoptosis inhibitor, P33 but contains serpins known to inhibit apoptosis in ChPVs. The ITRs of ACEV and CBEV are in the order of 23–24 kb, which are significantly longer than those in other EPVs (Table 2). Also, in the terminus of each ITR of ACEV, there is a concatemer resolution motif, which has been reported to be essential for resolving concatemeric DNA during replication of ChPV genomes.

Gene Families

EPVs contain genes that can be assembled into seven gene families (Table 3). Of these families, the AMEV genome contains 23 genes in six families and MSEV has 43 genes in five families. To date, the function of these genes has not been ascertained. However, it is quite reasonable to assume that the ALI (alanine-leucine-isoleucine) family members and 17K ORF family play functional roles in transcription and replication of DNA. The ALI gene family is characterized by an amino-terminal motif that contains invariant residues of alanine, leucine, and isoleucine. With the exception of AMV257, all members of the ALI motif family contain the Bro-N domain (N-terminus of baculovirus BRO proteins). The function of the baculovirus BRO proteins is still not clear but has been suggested that they are DNA binding proteins and may also be involved in regulating host DNA replication and/or transcription. The 17K ORF gene family is comprised of five AMEV proteins and homologs of the 17K ORF of *Heliothis armigera* entomopoxvirus (HAEV). This family has a putative DNA binding domain (KilA-N domain) present in many proteins in eukaryotic and bacterial DNA viruses, which implies a role in transcription and/or replication.

Entomopoxvirus Phylogeny

A variety of methods have been employed in phylogeny analysis including morphological, gene contents, order and arrangements or even individual genes. Relatively recently, single nucleotide polymorphism (SNP) and alignment-free methods have been used to illustrate phylogeny of poxviruses. Collinearity between any two genomes reflects conservation of genes and their order within the genomes. Based on phylogeny of concatenated amino acids of the 49 core genes, MSEV was observed to be distinctly divergent from betaentomopoxviruses. Similarly, phylogeny based on spheroidins revealed that the betaentomopoxviruses cluster together and are divergent from the alphaentomopoxviruses and deltaentomopoxviruses (Fig. 9). Indeed, a new genus was proposed, now called *Deltaentomopoxvirus* and comprising orthopteran EPVs: MSEV, *Calliptamus italicus* EPV (CIEV), *Gomphocerus sibiricus* EPV (GSEV), *Oedaleus asiaticus* EPV (OAEV), and *Anacridium aegyptium* EV (AAEV). These five EPVs are evolutionarily divergent from the alpha- and betaentomopoxviruses. Among the same genes, betaentomopoxviruses have a low degree of identity with MSEV. For example, spheroidin is about 20% identical between MSEV and other betaentomopoxviruses such as AMEV, CBEV, HAEV as well as the spheroidins of the alphaentomopoxviruses, MMEV and ACEV. In contrast, 76%–92% amino acid identity was detected among betaentomopoxviruses spheroidins. Moreover, the organization and gene order among the lepidopteran betaentomopoxviruses are quite conserved particularly the central region in the genomes. Such conservation is not observed between betaentomopoxviruses and those unassigned in the classification scheme. The molecular data that revealed the divergence between betaentomopoxviruses and MSEV validate the decision by the ICTV to remove the latter from the genus *Betaentomopoxvirus* and reclassify it as member of the *Deltaentomopoxvirus* genus.

While some virus groups such as EPVs and BVs have descended from different ancestral origins, they evolved to have remarkably similar processes of infecting the natural host. Analysis by secondary structure alignments revealed 33 clusters of homologous genes to be common to EPVs and BVs and not surprisingly, *DNA polymerase* is among the homologous clusters. The genes were independently acquired from the insect host, other viruses, eukaryotes and bacteria. This gene acquisition convergence may indicate adaptations to conserved interactions of the virus with the natural host. In fact, 15 genes appear to have been acquired by EPV and BV core genomes from the natural host by horizontal gene transfers.

Acknowledgment

We are indebted to Ms. Erika Provenzano for expending time and effort in literature searches and procuring relevant published manuscripts to aid in the preparation of this review.

Genomics research on EPVs was supported by a major grant from Genome Canada through the Ontario Genomics Institute and three grants from the Scientific and Technological Research Council of Turkey, TUBITAC.

It is acknowledged that Figs. 5, 6 and 9 have been published previously in the book "Insect Virology", Caister Academic Press, Norfolk, UK. The publisher is hereby acknowledged.

Glossary

Diptera (also known as true flies) An order of insects that comprises mosquitoes, gnats, midges, sand flies, and other flies. They possess a single pair of wings on the mesothorax (the middle of the three segments of the thorax of an insect) and a pair of halteres which are derived from the hind wings present on the metathorax (the posterior of the three segments of the thorax of an insect). The name is derived from the number of wings (*di* means two in Greek and *pteron* refers to the wings).

Hymenoptera This order of insects comprises the sawflies, wasps, bees, and ants. The name refers to the membranous wings of the insects and is derived from ancient Greek (*hymen*: membrane and *pteron*: wings). The hind wings of hymenopterans are connected to their forewings by hooks.

Lepidoptera This order of insects comprises butterflies, skippers, and moths. The name is derived from ancient Greek and refers to the minute scales (*lepidon*) that cover the membranous lanceolate wings (*pteron*) of adults.

Reovirus A virus in the family *Reoviridae* characterized by an icosahedral capsid of about 80 nm with one or two shells encompassing a segmented (usually 10–12) dsRNA genome with an aggregate size of about 25 kb. The name reovirus comes from respiratory enteric orphan virus, since these viruses caused respiratory and enteric infections. Since they were originally thought not to be associated with disease they were erroneously considered orphan viruses.

RNA dependent RNA polymerase (RdRp) An RNA polymerase which produces an RNA product from an ssRNA template.

Introduction

As a group, the reoviruses have a broad host range, including insects, algae, fungi, fish, crustaceans, crabs, humans and other vertebrates and their invertebrate vectors and plants and their invertebrate vectors. Since the 2008 Encyclopedia of Virology 3rd Edition, the

Reoviridae family in the Ninth Report of the International Taxonomy of Viruses in 2009, was subdivided into two subfamilies, *Sedoreovirinae* with six genera and *Spinareovirinae* with nine genera. The two subfamilies differ in the nature of the virion surface with the *Spinareovirinae* having a turreted or “spiked” surface (hence the prefix “Spina”, Latin for spike) while the *Sedoreovirinae* have a smooth surface (“Sedo” is Latin for smooth). Of the more recognized reoviruses are those infecting humans, other mammals and other vertebrates. Those from *Rotavirus* and *Orthoreovirus* genera infect only vertebrates, while viruses in genera *Coltivirus* (e.g., Colorado tick fever virus), *Orbivirus* (e.g., bluetongue virus) and one virus in genus *Seadornavirus* are considered arboviruses which infect both vertebrates and their invertebrate vectors (mostly ticks, mosquitoes, midges, gnats and sandflies). Lesser known reoviruses infect algae (*Mimovirus*) and fungi (*Mycovirus*). In addition to infecting plants, reoviruses in genera *Fijivirus*, *Oryzavirus* and *Phytovirus* also infect their insect vectors (grasshoppers). These are described in more detail in the article on *Reoviridae* in this Encyclopedia.

There are also reoviruses that infect exclusively invertebrates. There are many reoviruses infecting only insects in the genera *Cypovirus* and *Idnoreovirus*. Other reoviruses infecting only insects are found in genera *Dinovernavirus*, *Fijivirus*, *Orthoreovirus*, *Pytoreovirus* and *Seadornavirus*. Reoviruses in two genera *Aquareovirus* and *Cardoreovirus*, infect only crustaceans including oysters and crabs, some of economic importance.

Like other reoviruses, the reoviruses of invertebrates have a single or double shelled icosahedral capsid with diameters ranging from 60 to 80 nm (though idnoreovirus capsids are smaller at about a 50 nm diameter). While cypoviruses and dinovernaviruses have a single shell with $T=2$, aquareoviruses, coltivoruses, idnoreoviruses, cardeoviruses, phytoviruses and seadornaviruses have two shells, the inner with $T=2$ and the outer layer with $T=13$ icosahedral symmetry. They have 8–12 dsRNA segments. These range in size from 0.76 to 4.47 kb with each segment, in general, encoding one protein. For cypoviruses, segment 5 encodes two proteins by ribosomal skipping. Aggregate genome sizes range from 18.1 kb to 25.72 kb (although a size of 32.7 kb was reported for an unclassified *Dendrolimus punctatus* cypovirus). With a G + C content (based on those reoviruses whose whole genomes have been sequenced) ranging from 33.25% to 43.81%.

Morphology, infection and replication of the invertebrate reoviruses closely mimic that of other reoviruses and will be covered only briefly here. Instead, the reader is referred to the article in this Encyclopedia on Reoviruses (*Reoviridae*) and Their Structural Relatives.

Spinareovirinae

Much of the material on the *Spinareovirinae* viruses in this article is based on Insect Reoviruses by Peter Mertens and Houssam Attoui in the previous, 3rd, edition of the Encyclopedia of Virology and provided a good foundation for this update.

Some spinareoviruses infecting only invertebrates are found in genera *Cypovirus* (insects), *Dinovernavirus* (mosquitoes) and *Idnoreovirus* (hymenoptera and diptera). One reovirus in genus *Aquareovirus* (which as the name implies, infect aquatic animals) infects only oysters, while others in the same genus infect vertebrates like fish. In the genus *Fijivirus* of plant-infecting reoviruses, one virus, *Nilaparavata lugens* reovirus, has been found only in plant hoppers. One virus in genus *Orthoreovirus*, *Mahlapitsi orthoreovirus* infects only bat flies, while Chiqui virus, another, unclassified, orthoreovirus was isolated from mosquitoes. [Table 1](#) summarizes the recognized species in the *Spinareovirinae* with viruses infecting invertebrates within the six genera listed above.

Of the *Spinareovirinae* insect reoviruses, most cypoviruses have 10 dsRNA segments but can have 8, 11 or even 16 segments (*Dendrolimus punctatus* cypovirus) and infect lepidoptera like *Lymantria dispar* (Gypsy larvae) and one infects the hymenoptera *Polistes hebraeus*. Idnoreoviruses have 10 dsRNA segments and infect hymenoptera like *Diadroma pulchellas* (a hymenopteran parasitoid) and diptera like *Musca domestica*. Dinovernavirus has 9 dsRNA segments and was found in an *Aedes* mosquito AP61 cell line.

Cypovirus was the first invertebrate reovirus discovered and that was in 1934 as polyhedra in the cytoplasm of infected cells of silkworm larvae and hence were initially named cytoplasmic polyhedrosis viruses from which the current genus name was derived. Aquareoviruses (*Aqua* for their common aqueous environment of their hosts) have been isolated from oysters and crabs. Idnoreoviruses (from “idno” meaning water) were first isolated from houseflies in 1978, while the lone dinovernavirus (from double stranded RNA icosahedral *nove*, meaning nine, dsRNA segments *RNA*) was isolated from a cell line from *Aedes pseudoscutellaris* in 2005.

The cypoviruses can produce severe to chronic diseases in their infected hosts and represent one of the most significant threats to the silkworm industry. The idnoreoviruses have a core structure that is directly comparable to the cypovirus virion but they also have an additional ‘outer layer’ of capsid proteins. They do not usually cause a cytopathic effect or disease in their insect hosts but may be involved in modifying the phenotype or sex of the host insect. The dinovernaviruses have been isolated only from cultured insect cells and like cypoviruses have a single-shelled capsid, but do not produce polyhedra.

The *Cytoplasmic polyhedrosis virus* group was initially recognized as a genus name with viruses infecting insects in 1971 by the International Committee on Taxonomy of Viruses (ICTV). Unlike baculoviruses which replicate in the nucleus, these viruses replicate and produce polyhedra in the cytoplasm, giving rise to their name as cytoplasmic polyhedrosis viruses. By 1990 the genus name was changed to *Cypovirus* (sigla: *cytoplasmic polyhedrosis virus*) and recognized by ICTV. Cypovirus particles are ~70 nm in diameter, contain a segmented dsRNA genome of 10 segments, and belong to the “turreted” reoviruses, with surface projections (turrets) situated at each of the 12 “fivefold” vertices. Unlike most other reoviruses, cypoviruses are single-shelled, with no outer capsid layer. Cypoviruses have one unique feature among reoviruses in that they form polyhedra which can retain infectivity for years. The major polyhedrin protein is translated in large excess in the cytoplasm late in infection and virions are occluded in the polyhedrin at the periphery of the virogenic stroma in which morphogenesis of the virions occurs and in which virus particles become singly or multiply embedded. More than 230 cypovirus isolates have been described, with evidence for at least 22 distinct species (based on differences in the migration pattern of their genome segments during electrophoresis–electropherotype and

^a*Nilaparvata lugens* reovirus is the only fijivirus which infects exclusively insects (plant hoppers). All other fijiviruses infect plants and their invertebrate vectors.

^b*Mahlapitsi orthoreovirus* is the only orthoreovirus which infects exclusively insects (bat flies), all other orthoreoviruses infect only vertebrates.

nucleotide sequence divergence). However, very few cypoviruses have so far been isolated from Africa, and undoubtedly many more species are sure to be recognized.

The genus *Idnoreovirus* (sigla: insect-derived nonoccluded reovirus) was formally recognized by ICTV in 2005. *Idnoreoviruses* have ten segmented dsRNA genomes and are icosahedral particles, ~70 nm in diameter with a turreted “core”. However, unlike the cypoviruses, they also have an outer capsid protein layer and do not produce polyhedra. *Idnoreoviruses* have been isolated from various flies including the fruit fly, the small fruit fly (*drosophila*), the olive fly, and housefly. They have also been isolated from parasitic wasps.

The genus *Dinovernavirus* (sigla: double-stranded insect, novem (nine in Latin, the number of genome segments) *RNA virus*) includes the first nine-segmented dsRNA virus. Like the cypoviruses, *dinovernaviruses* are single-shelled, turreted, and lack an outer capsid layer, but do not produce polyhedra or a “polyhedrin” protein.

While the genus *Aquareovirus* contains mostly reoviruses that infect fish like salmon, shiner and catfish, one virus in species *Aquareovirus A*, American oyster reovirus, infects oysters and have been isolated from Geoduck, shore, swimmer and mitten crabs.

This virus has 11 dsRNA segments. Virions are about 80 nm in diameter and have multiple capsid layers. The viruses replicate efficiently in fish and mammalian cell lines within a temperature range of 15–25°C.

While most viruses in the genus *Fijivirus* infect plants one *fijivirus*, *Nilaparvata lugens* reovirus (NLRV) has been found exclusively in planthopper but does not seem to replicate in rice. Nevertheless the virus can be transmitted from hopper to hopper through contaminated rice plants. Virions are double shelled icosahedra about 65–70 nm in diameter with 10 dsRNA segments ranging from 1.43 to 4.39 kp in size. The NLRV RNA genome has a G + C content of 34.9% and an aggregate size of 28.7 kb.

Virus members of the genus *Orthoreovirus* are vertebrate viruses usually spread through the fecal oral route. However, one orthoreovirus, *Mahlapitsi orthoreovirus*, infects bat flies and Chiqui virus was found only in mosquitoes. While most orthoreoviruses have a genome of 10 dsRNA segments, the *Mahlapitsi orthoreovirus* has 11 segments ranging in size from 1.07 to 3.93 kb with an aggregate size of 23,195 bp and a G + C content of 43.81%. Chiqui virus has 9 dsRNA segments ranging in size from 1.15 to 4.01 kb, an aggregate size of 25,028 bp and a G + C content of 36.20%.

Historical Overview

Cypoviruses were first recognized by Ishimori in 1934, who observed polyhedra in the cytoplasm of midgut cells of diseased silkworm larvae. Cytoplasmic polyhedrosis has subsequently been recognized as an important cause of economic losses in the Japanese sericulture industry. Cypoviruses have a wide host range, infecting many lepidopteran insect species (more than 200 host species have been identified). Recent reports of cypovirus infections in mosquitoes confirm that they can also infect Diptera. The high levels of sequence divergence between equivalent genome segments of different cypovirus species, and the large numbers of distinct species, suggest that this is an ancient group. Indeed, cypoviruses have been detected in biting midges trapped in amber, indicating that they existed almost 100 million years ago.

The American oyster reovirus in genus *Aquareovirus* was first identified in 1979 in *Crassostrea virginica* by J.R. Winton and colleagues and was later characterized as a reovirus with 11 dsRNA segments in 1987.

The genus *Dinovernavirus* currently contains a single species (*Aedes pseudoscutellaris dinovernavirus*; the virus *Aedes pseudoscutellaris dinovernavirus* 1 (ApDNV-1)) was isolated in 2005 from the AP61 cell line established by Varma *et al.* from the mosquito *Aedes pseudoscutellaris*.

The first idnoreovirus was isolated from the housefly *Musca domestica* in 1978. Several other idnoreoviruses have been isolated. *Diadromus pulchellus idnoreovirus* 1 (DpIRV-1), the most recently isolated idnoreovirus, has a genome composed of 10 dsRNA segments in functional male insects, with an additional segment (derived from genome segment 3) in particles isolated from females or sterile male wasps.

The first report of an insect reovirus in genus *Fijivirus* was in 1991 when Noda and colleagues found *Nilaparvata lugens* reovirus in apparently healthy brown planthoppers *Nilaparvata lugens* and then characterized it as a reovirus with 10 dsRNA segments. Other *fijiviruses* infect plants and their invertebrate vectors.

An insect orthoreovirus in the genus *Orthoreovirus* was first described by PJ Van Vuren and colleagues in 2016 when they isolated *Mahlapitsi orthoreovirus* from bat flies, *Eucampisipoda Africana* associated with African bats *Rousettus aegyptiacus* in South Africa. As part of their studies they determined the sequence of the 10 dsRNA segments determining an aggregate genome size of 23,195 bp and a G + C content of 43.81%. A second invertebrate orthoreovirus was Chiqui virus which was isolated from mosquitoes collected in Columbia by M.A. Contreras-Gutierrez in 2018. Based on genome sequencing of the 9 dsRNA segments with an aggregate size of 25,028 bp and G + C content of 36.20%, they concluded that Chiqui virus was in the subfamily *Spinareovirinae*.

Host Range, Diseases, Transmission, and Distribution

Cypoviruses

Cypoviruses have been isolated from only arthropods, including members of over 45 genera of Lepidoptera. However, they have also been isolated from Hymenoptera, including the wasps *Polistes hebraeus* and *Diadromus pulchellus*, and from Diptera, including the mosquitoes *Culex restuans* and *Uranotaenia sapphirina*. One isolate was reported from the freshwater daphnid *Simocephalus expinosus*. Experimental studies indicate that cypoviruses cannot infect mammals or mammalian cell cultures.

The majority of cypovirus infections produce chronic disease, often without extensive larval mortality. Consequently, many individuals become adults even though they are heavily diseased. Infected larvae can stop feeding as early as 2 days post infection, producing symptoms of starvation. Their body size and weight are often reduced and diarrhea is common. The duration of the larval stage can also increase by ~1.5 times. Infected pupae are frequently smaller and many diseased adults do not emerge correctly, can be malformed, and flightless. Infected females may exhibit a reduced egg-laying capacity.

Cypoviruses can be transmitted on the surface of eggs, producing high levels of infection in the subsequent generation. However, disinfection of the egg surface destroys the virus, indicating that cypoviruses are not transovarially transmitted. The minimum infectious dose increases dramatically in later larval instars, although virulence varies significantly with virus strain and host species. Larvae can sometimes recover from cypovirus infections, possibly because the gut epithelium has considerable regenerative capacity and infected cells are shed at each larval molt.

Cypoviruses are normally transmitted by an oral–fecal route. Ingested polyhedra on contaminated food materials dissolve in the high pH environment of the insect gut, releasing occluded virus particles, which can then infect the cells lining the gut wall.

Infection is generally restricted to the columnar epithelial cells of the larval midgut, although goblet cells may also become infected. Cypovirus infection spreads throughout the midgut region (and sometimes infect the fat body), although infection of the entire gut has occasionally been observed in some species. The production of very large numbers of polyhedra gives the gut a characteristically creamy-white appearance. The endoplasmic reticulum of infected cells is progressively degraded, mitochondria enlarged, and the cytoplasm becomes highly vacuolated. In most cases, the nucleus shows few pathological changes. However a cypovirus strain has been detected that produces polyhedra within the cell nucleus. In the later stages of infection, cellular hypertrophy is common and microvillae are reduced or absent. Polyhedra are released into the gut lumen by cell lysis and are excreted. The gut pH is lowered during infection preventing dissolution of progeny polyhedra in the gut fluid.

Idnoreoviruses

All known members of the genus *Idnoreovirus* infect insects, with host species that include *Diadromus pulchellus* and *Hyposoter exiguae* (wasps: Hymenoptera); *Musca domestica* (housefly); *Dacus oleae* (olive fly); *Ceratitis capitata* (Mediterranean fruit fly); and *Drosophila melanogaster* (small fruit fly) (flies: Diptera).

Unlike the cypoviruses, idnoreoviruses appear to cause few pathological effects in their hosts, although they may significantly influence the biological properties of individual insects. *Drosophila S* virus appears to be associated with the “S” phenotype in *D. simulans* (a maternally inherited morphological trait associated with abnormal bristles). The presence of an additional 3.33 kb dsRNA segment in DpIRV-1 is related to the sex and ploidy of the host, and may play a role in the biology of the host wasp species, possibly by providing information necessary for larval development.

Dinovernavirus

ApDNV-1, the only representative of this genus, was isolated from persistently infected *A. pseudscutellaris* cells.

Aquareovirus

American oyster reovirus 13p2 is the only aquareovirus not isolated from vertebrates but rather from oysters. Although it was originally isolated from oysters, the virus can replicate in Golden shiner fish at temperatures of 23 and 28°C.

Fijivirus

Unlike other fijiviruses which replicate in plants and their invertebrate vectors, *Nilaparvata lugens* reovirus replicates only in invertebrates, specifically the brown planthopper *Nilaparvata lugens* and transmission appears to involve contaminated rice plants. The virus does not appear to replicate in rice.

Orthoreovirus

While most orthoreoviruses infect vertebrates including mammals, birds and reptiles, only two orthoreoviruses, Mahlapitsi orthoreovirus and Chiqui virus infect invertebrates, specifically bat flies and mosquitoes, respectively.

Virion Properties, Genome, and Replication

Cypoviruses

Large proteinaceous inclusion bodies are characteristically produced during cypovirus infections, usually within the cytoplasm of infected insect cells. The crystalline matrix of these “polyhedra” is primarily composed of a single viral “polyhedrin” protein that is often encoded by the smallest genome segment (Seg-10). The polyhedrin structure appears to protect the occluded virus particles, possibly filling the role of outer capsid proteins found in other reoviruses. Polyhedra are frequently symmetrical (cubic, icosahedral, or irregular) depending on both the virus strain (polyhedrin sequence) and the host species. The polyhedrin molecules appear to be arranged as a face-centered cubic lattice with center-to-center spacing varying between 4.1 and 7.4 nm. In some virus species, the virus particles are occluded singly within small occlusion bodies, which can also aggregate. However, some cypoviruses produce large polyhedra containing large numbers of particles, often regularly spaced within the polyhedrin matrix. “Empty” polyhedra containing no virus particles have also been observed.

Cypovirus particles have a single-layered capsid, composed of a central shell, ~57 nm in diameter (by cryoelectron microscopy), which extends to 71.5 nm when the 12 “turrets” or “spikes” on the icosahedral fivefold vertices are included. These turrets are hollow, up to 20 nm in length and 15–23 nm wide (by conventional electron microscopy and negative staining). The cypovirus capsid has a central compartment, ~35 nm in diameter, which normally contains the genomic dsRNA segments.

Cypovirus virions are structurally comparable to the cores of other reoviruses, particularly those from the genera with “turreted” cores (e.g., *Orthoreovirus*, *Aquareovirus*, and *Oryzavirus*) (Figs. 1 and 2). Cypovirus particles generally contain five to six distinct proteins, three of which have been identified as the T2 protein (120 copies, equivalent to the VP3(T2) subcore shell protein of bluetongue virus, or orthoreovirus lambda1); “large protrusion protein” (LPP, 120 copies, comparable to orthoreovirus sigma2); and “turret protein” (TP, 60 copies, comparable to orthoreovirus lambda2). Cypoviruses also contain transcriptase enzyme complexes attached to the inner surface of the capsid shell at the icosahedral fivefold vertices. Two or three of the cypovirus structural proteins are usually > 100 kDa.

Fig. 1 Electron micrographs of cypovirus, dinovirnavirus, and idnoreovirus particles. (a) Contrast electron micrograph of nonoccluded *Orgyia pseudosugata* cypovirus 5 (OpCPV-5) virion. (b) Contrast electron micrograph of *Aedes Pseudoscutellaris* reovirus particles. The bars represent 20 nm. (c) Electron micrographs of purified virus particles (left) and core particles (right) of *Hyposoter exiguae* idnoreovirus-2 (HeIRV-1) stained with uranyl acetate. (d) Electron micrographs of a virus particle (left) and core particle (right) (stained with sodium phosphotungstate) of purified *Dacus oleae* idnoreovirus-4 (DoIRV-4). DoIRV-4 virions have small icosahedrally arranged surface projections (probably up to 12 in number), while the cores show much larger 'spikes' or 'turrets', which may lose a portion near to the tip (like those of the cypoviruses). (a) Courtesy of C. L. Hill. (c) Courtesy of Andrea Makkay and Don Stoltz. (d) Courtesy of Max Bergoin.

The structural proteins of *Bombyx mori* cypovirus 1 (BmCPV-1) are 148 (VP1), 136 (VP2), 140 (VP3), 120 (VP4), 64 (VP6), and 31 kDa (VP7) (Table 2). Polyhedra also contain the 25–37 kDa "polyhedrin protein" (28.5 kDa for BmCPV-1) which represents approximately 95% of the polyhedra protein (by dry weight). The buoyant density of virions in CsCl is 1.44 g cm^{-3} , c. 1.30 g cm^{-3} for empty particles, and 1.28 g cm^{-3} for polyhedra. Due to the high level of variation among different cypoviruses, it is unlikely that their homologous proteins can be identified simply by their migration order during polyacrylamide gel electrophoresis (PAGE).

Cypoviruses retain infectivity for several weeks at -15 , 5 , or 25°C . The virus retains full enzymatic activity (dsRNA-dependent single-stranded RNA polymerase and capping activity) even after repeated freeze–thawing (up to 60 cycles), even though this disrupts the virus particle into ten active but distinct enzyme/template complexes. Each transcription complex contains one genome segment and a complete transcriptase complex that includes one of the 'spike' structures derived from the fivefold axes of the virion capsid.

Cations have relatively little effect on cypovirus structure. Heat treatment of virions at 60°C for 1 h leads to degradation and release of genomic RNA. Virus particles are relatively resistant to treatment with trypsin, chymotrypsin, ribonuclease A, deoxyribonuclease, or phospholipase. Virion enzyme functions also show some resistance to treatment with proteinase K. However, this

Seg-8	1328	VP5 (NSP8)	Unknown (anomalous PAGE migration at 55 kDa)
Seg-9	1186	NS5 (NSP9)	Nonstructural, dsRNA binding
Seg-10	994	Polyhedrin	Polyhedrin protein (Pod)

^aNS1 (NS5): cleaved into NS2 (NS5a) and NS6 (NS5b). RdRp, RNA-dependent RNA polymerase.

Note: From information available at: http://www.iah.bbsrc.ac.uk/dsRNA_virus_proteins/BmCPV-1.htm.

Under the 'Protein' heading, an alternative nomenclature for the viral proteins is given in brackets. The nomenclature that is used in the Eighth Report of the ICTV and presented on the website: http://www.iah.bbsrc.ac.uk/dsRNA_virus_proteins/protein-comparison.htm.

may reflect retention of enzyme activities despite particle disruption, particularly during the early stages of digestion. Cypovirus particles are resistant to detergents including sodium deoxycholate (0.5%–1%) but are disrupted by 0.5%–1% sodium dodecyl sulfate (SDS), which releases the genomic dsRNA. Treatment with triton X-100, NP40, or urea also causes disruption of the virus

Fig. 3 The genomes of dinovernaviruses and cypoviruses. Genome electropherotypes of members of genera *Dinovernavirus* (ApDNV-1) and *Cypovirus* (CPV – 1, – 2, – 3, and – 8). The segment position is indicated to the right of each profile.

particle structure. One or two fluorocarbon treatments have little effect on virus infectivity, though treatment with ethanol leads to release of RNA from virions. Viruses and polyhedra are readily inactivated by ultraviolet (UV) irradiation which dissociates the dsRNA template from the transcriptase complexes. Polyhedra remain infectious for years at temperatures below 20°C. Virions can be released from polyhedra by treatment with carbonate buffer at pH greater than 10.5 but are disrupted below pH 5. As in permissive insects' midguts, high pH treatment completely dissolves the polyhedral protein matrix. This process is partly due to increased solubility of polyhedrin at high pH but is also aided by alkaline-activated proteases associated within the polyhedra.

Polyhedra (but not virions) contain significant amounts of adenylate-rich oligonucleotides. In the majority of cases, cypovirus particles contain 10 dsRNA genome segments. However, virus particles containing an 11th small segment (e.g., *Trichoplusia ni* cypovirus 15, TnCPV-15 and *Antheria mylitta* cypovirus 4), 8 segments (in *Choristoneura fumiferana* cypovirus 16 and unclassified *Daphnia merii* cypovirus) and up to 16 segments (in unclassified *Dendrolimus punctatus* cypovirus 22) have been detected. The genome segments of BmCPV-1 vary from 4,190–994 bp with a total genome size of 24,809 bp. The genome segments of other cypoviruses have been estimated by electrophoretic comparisons, and have calculated sizes between 5.6 and 0.6 kb, with a total genome size of 29.2–33.3 kb.

The size distribution of the genome segments varies widely among different cypoviruses (e.g., the smallest dsRNA has an estimated size that varies between 0.53 and 1.44 kb). These size differences formed the initial basis for recognition and classification of distinct species (electropherotypes) of cypoviruses (which differ significantly in the migration of at least three genome segments during electrophoresis using 1% agarose or 3% SDS-PAGE). The genome segment migration patterns of types 1, 12, and 14 have some overall similarity, suggesting that they are more closely related than some other cypoviruses (Fig. 3). More accurate sizes are derived from whole genome sequencing (Table 1). By sequence analysis, the aggregate sizes of cypoviruses ranges from 18,088 bp to 25,325 bp, although the largest size of 32,753 bp was reported for *Dendrolimus punctatus* cypovirus 22. Aggregate G + C content ranges from 36.42% to 43.22%. The smallest segment was 0.88 kb (*Heliothis armigera* cypovirus 5) and the largest was 4.44 kb (*Lymantria dispar* cypovirus 14).

The termini of different genome segments within a single cypovirus species are often highly conserved but differ from those reported for other species (Table 3). *Choristoneura fumiferana* cypovirus 16 (CfCPV-16) shows high levels of sequence variation when compared to CPV-1, -2, -5, -14, or -15 and is therefore considered to be a distinct species, even though it has a similar 5' end but different 3' ends to representatives of CPV-5. These data demonstrate that different cypovirus electropherotypes are likely to have different conserved RNA terminal sequences.

Large size variations in the genome segments of most cypovirus species (apart from CPV-1, -12, and -14) indicate that the gene assignments for one "type" or species cannot simply be applied to the other cypoviruses. Genome segment coding assignment by *in vitro* translation of individual genome segments have been published for isolates of CPV-1 and -2. These data and subsequent sequencing studies indicate that the polyhedrin protein is often encoded by the smallest segment.

Cypovirus uptake appears to be a relatively inefficient process in insect cell cultures but can be significantly improved by lipofection. Liposomes deliver cypovirus particles into the cytoplasm where replication occurs. Cypoviruses do not require particle modification to activate transcriptase and capping enzymes. The outer coat proteins of other reoviruses need to be removed to activate transcription. Cypovirus polymerase activity can show very pronounced dependence on the presence of S-adenosyl-l-methionine or related compounds, although this varies between different cypovirus species.

Virus replication and assembly occur within the host cell cytoplasm, although viral RNA synthesis can sometimes occur within the nucleus. Replication is accompanied by the formation of viroplasm (virogenic stroma or "VIB") within the cytoplasm, containing

large amounts of viral proteins and virus particles. The mechanism used to select the individual genome segments for packaging and assembly into progeny particles (exactly one copy of each segment) is unknown. The importance of the conserved terminal regions in this process is indicated by packaging and transcription of a mutant Seg-10 of CPV-1 that contained only 121 bp from the 5' end and 200 bp from the 3' end. Particles are occluded within polyhedra apparently at the periphery of the VIB, from about 15 h post-infection onward. The polyhedrin protein is produced late in infection and in large excess compared to the other viral proteins. It is unknown how polyhedrin synthesis is regulated.

Idnoreoviruses

Electron microscopy and negative staining of the idnoreovirus particles show that they have no prominent features, are spherical in appearance (icosahedral symmetry), and ~70 nm in diameter. However, they do have a clearly defined outer capsid layer that can be removed to reveal the virus core. Unlike the cypoviruses, idnoreoviruses do not encode a polyhedrin protein, and the virus particles are "nonoccluded". Idnoreovirus core particles have an estimated diameter of ~60 nm, with 12 icosahedrally arranged surface "turrets" or "spikes".

Limited studies of some viruses within the genus indicate that they are resistant to freon (trichlorotrifluoroethane) and CsCl. They may also be resistant to chymotrypsin. Intact virus particles and cores of the prototype isolate *Diadromus pulchellus* idnoreovirus-1 (DpIRV-1) have densities of 1.370 and 1.385 g ml⁻¹, respectively, while intact virions and empty particles of *Dacus oleae* idnoreovirus-4 (DoIRV-4) have a density of ~1.38 and ~1.28 g ml⁻¹, respectively (determined by CsCl gradient centrifugation). The outer capsid layer of *Hyposoter exiguae* idnoreovirus-2 (HeIRV-2) can be disrupted by brief exposure to 0.4% sodium sarcosinate, releasing the virus core.

The genome of most idnoreoviruses consists of 10 linear segments of dsRNA that are conventionally identified as "genome segment 1" to "genome segment 10" (Seg-1 to Seg-10) in order of reducing molecular weight and increasing electrophoretic mobility during agarose gel electrophoresis (AGE). The total genome of DpIRV-1 contains an estimated 25.15 kb of dsRNA, with individual segments ranging between ~4.8 and ~0.98 kb, and an electrophoretic migration pattern (by 1% AGE) showing five larger and five smaller segments (a "5/5" pattern). However, the virions of DpIRV-1 may be atypical since they can sometimes also contain an 11th, 3.33-kb genome segment, the presence of which is related to the sex and ploidy of the individual wasp host. This additional dsRNA (migrating between genome segments 3 and 4) contains sequences similar to and therefore possibly derived from Seg-3 (3.8 kb).

The genome segments of HeIRV-2 range in size from ~3.9 to ~1.35 kb, with a "4/6" electrophoretic migration pattern (by PAGE). DoIRV-4 contains an estimated 23.4 kb, with segments estimated from ~3.8 to ~0.7 kb and a "5/3/2" electrophoretic migration pattern (by PAGE). *Ceratitis capitata* idnoreovirus-5 (CcIRV-5) has a "3/3/4" genome segment migration pattern when analyzed by PAGE and has clear similarities to *Drosophila melanogaster* idnoreovirus-5 (DmIRV-5), suggesting that despite some

Table 4 Coding assignments for the DpIRV-1 genome segments

Seg-10	985	VP10	

Note: Seg-x: the supernumerary segment that is linked to the sex and ploidy of the insect host.

RdRp, RNA-dependent RNA polymerase.

More information is available at: http://www.iah.bbsrc.ac.uk/dsRNA_virus_proteins/Idnoreovirus.htm.

serological differences, they belong to the same virus species, specifically *Idnoreovirus* 5. It is unclear how closely drosophila S virus is related to the other drosophila viruses. It is therefore, currently, classified as a “tentative species” within the genus.

By analogy with other reoviruses (e.g., the orbiviruses), genome segment migration patterns (by AGE) are likely to be characteristic of each *Idnoreovirus* species. Initial sequencing studies suggest that the 3' termini of DpIRV-1 genome segments are more variable than most other reoviruses with little sign of conservation. However, conserved sequences were detected at the 5' termini (Table 3), which are different from those of other reovirus species. Except for the sequences of 6 segments from DpIRV-1, no sequence data are currently available for other members of this genus.

Although the proteins of DpIRV-1 have not been extensively characterized, purified virions contain 11 structural proteins with M_r 21–140 kDa (as analyzed by SDS-PAGE). Three of these appeared to be glycosylated (M_r approximately of 21, 15, and 35 kDa). Some of the viral genome segments have been sequenced (as indicated in Table 4). The viral proteins are named as VP1–VP10 based on the molecular weight of the genome segment (segment number) from which they are translated.

On the basis of their structural and biochemical similarity, it seems likely that many aspects of the genome organization and replication of the idnoreoviruses will show similarities to those of other reoviruses (particularly the other turreted spinareoviruses). On this basis it is likely that the virus core will contain transcriptase complexes that synthesize mRNA copies of the individual genome segments. These will be exported and translated to produce the viral proteins within the host cytoplasm. These positive-sense RNAs are also likely to form templates for negative-strand synthesis during progeny virus assembly and maturation. The genome segments that have been characterized represent single genes, with a large ORF, and relatively short noncoding terminal regions.

Dinovernavirus

Transmission electron microscopy of ApDNV (the prototype and only dinovernavirus) showed that purified virions have a structure similar to core particles of turreted reoviruses (Fig. 1(b)), with particular similarities to the single-shelled cypoviruses, with no outer capsid layer. The mean diameter of the virus particle is ~49–50 nm, with a central space (for the viral genome) that is 36–37 nm in diameter. Turrets were clearly visible projecting from the particle surface.

The infectivity of ApDNV-1 particles is destroyed by treatment with 0.1% SDS but unaffected by 1% deoxycholate or repeated treatments with Freon 113 or Vertrel-XF. Freezing at –20 or –80°C, or heating to 50–60°C for 30 min abolished ApDNV infectivity, even in presence of 50% fetal bovine serum (FBS). However, infectivity was stable for up to 3 weeks at room temperature and for at least 5 months at 4°C. ApDNV is stable at pH 6–8, but infectivity was reduced tenfold at pH 4–5 or pH 9–10. The virion morphology (observed by electron microscopy) becomes distorted below pH 5 and is completely disrupted below pH 3.5.

ApDNV persistently infects AP61 cells without any visible cytopathic effects and has been detected in these cells from several different sources. The number of copies of the ApDNV genome in each persistently infected AP61 cell was estimated by quantitative polymerase chain reaction (PCR) as between 1 and 5, although treatment with 2-aminopurine (2-AM) can increase the number to 60–80 genome copies per cell. The virus can also infect and replicate in mosquito cells, including AA23 and C6/36 (from *Aedes albopictus*) cells and A20 cells (from *Aedes aegypti*), but not in AE cells (*A. aegypti*) or Aw-albus (*Aedes w-albus*). ApDNV failed to replicate in mammalian cells or in mice.

Unlike other reoviruses, the genome of ApDNV contains only 9 segments of dsRNA, with a 4/1/3 AGE migration profile (Fig. 3). The aggregate genome size is 23,147 bps and the 9 dsRNA segments range from 1.15 to 3.82 kb in size. The G + C content is 33.95% compared to 34.8% for fijiviruses, 44.7% for oryzaviruses, 43% for the cypoviruses, and 63% for idnoreoviruses. The termini of ApDNV contain conserved terminal sequences (Table 3). The first three nucleotides “AGU” are conserved between ApDNV, some fijiviruses, and some cypoviruses; though, unlike the cypoviruses and fijiviruses, the first and last nucleotides of the ApDNV genome segments are complementary (A and U). The mean G + C content of the ApDNV genome is 34%.

Table 5 Coding assignments for the ApDNV-1 genome segments

Segment	Size (bp)	Protein	Function by similarity
Seg-1	3817	VP1	Possible cell attachment
Seg-2	3752	VP2	RdRp
Seg-3	3732	VP3	T2
Seg-4	3375	VP4	Nonstructural
Seg-5	3227	VP5	Possible capping enzyme
Seg-6	1775	VP6	Possible NTPase
Seg-7	1171	VP7	Nonstructural
Seg-8	1151	VP8	Possible translational regulation
Seg-9	1147	VP9	Viral inclusion bodies

Note: More information is available at: http://www.iah.bbsrc.ac.uk/dsRNA_virus_proteins/Dinovernavirus.htm.

The putative functions of ApDNV proteins VP1–VP9 (based on sequence similarities to other reovirus proteins) are shown in **Table 5**. These comparisons suggest that there is no equivalent to the cypovirus polyhedrin gene and appear to confirm the status of ApDNV as a distinct and authentic nine-segmented dsRNA reovirus.

Antigenic and Genetic Relationships

Cypoviruses

Cypoviruses are currently classified within 16 species that were initially identified by their distinctive dsRNA migration patterns. Cross-hybridization analysis of the dsRNA, serological comparisons of the viral proteins, and comparison of RNA sequences confirmed the validity of this classification and have identified further tentative species within the genus. However, only relatively few cypovirus isolates have been characterized, suggesting that there may be many more species yet to be identified.

Virus isolates within a single cypovirus electropherotype exhibit high levels of antigenic cross-reaction, as well as efficient cross-hybridization of their denatured genomic dsRNA, even under high-stringency conditions. In contrast, there is little to no evidence of serological cross-reaction between viruses from different electropherotypes (representing different cypovirus species). However, CPV-1 and CPV-12 are exceptions, showing a low but significant level of serological cross-reaction. These viruses also show some overall similarity in their electropherotype pattern and detectable levels of cross-hybridization of their genomic RNA. CPV-14 also shows some similarity in its RNA electropherotype pattern to both CPV-1 and CPV-12, suggesting that it may also show some antigenic relationship and RNA sequence homology with these viruses.

The nomenclature currently used to identify different cypovirus isolates takes account of both the virus species and the host species from which the virus was originally isolated (e.g., an isolate of CPV-1 from *Bombyx mori* would be identified as BmCPV-1). The sequence data that are available for isolates of CPV-1, -2, -5, -14, -15, and -16 allow a comparison of some genes from these viruses. There is significantly higher conservation in the largest genome segments (possibly as a result of functional constraints) although the level of variation is relatively uniform across the whole genome. Earlier cross-hybridization studies suggested that the level of nucleotide sequence variation is also relatively uniform across the whole cypovirus genome, possibly reflecting the absence of neutralizing antibodies (and therefore antibody selective pressure) in their insect hosts. Different isolates within a single cypovirus species usually show very high levels of nucleotide sequence identity. For example, different isolates of CPV-5 show >98% identity in genome Seg-10 (the polyhedrin gene), while different isolates of CPV-1 show 89%–98% nucleotide sequence identity in this gene. In contrast, comparisons of unrelated species showed only relatively low levels (20%–23%) of sequence identity (**Fig. 4**).

The level of amino acid (aa) identity in the putative viral polymerase varied from 92.9% to 99.5% within a single cypovirus type, and 42.3%–43.3% between different types (**Fig. 5**); (see **Table 6** for abbreviations and accession numbers).

Idnoreoviruses

Antigenic relations between different idnoreoviruses have not been analyzed. The phylogenetic relationship between different idnoreoviruses is also unknown (the genome of DpRV is the only idnoreovirus one sequenced to date). However, the sequence of DpRV shows homologies to other reoviruses (aa identities reaching up to 20% with fijiviruses, oryzaviruses, rotaviruses, sea-dornaviruses, and orbiviruses).

Dinovernaviruses

Sequence comparison of the *Aedes pseudoscutellaris* reovirus genome to other reoviruses has shown significant aa identities in each of the viral proteins. Members of the genera *Cypovirus*, *Oryzavirus*, and *Fijivirus*, which are also turreted, showed the highest aa identities (19%–31%). Amino acid identity values <30% between RdRps of the various reoviruses can be used to distinguish the

Fig. 4 Phylogenetic tree for polyhedrin proteins from isolates belonging to six *Cypovirus* species. The scale bar indicates the number of substitutions per site.

members of different genera. The relationship of ApDNV to other reoviruses is illustrated by a phylogenetic tree for the RdRp gene (Fig. 5). Although these sequence comparisons confirm the validity of ApDNV classification within a separate genus, they also indicate significant relationships with the turreted cypoviruses, fijiviruses, and oryzaviruses (aa identities of 26%, 23%, and 22%, respectively). Lower levels of aa identity (20%) were also detected with the mycoreoviruses (which are also turreted).

Sedoreovirinae

The *Sedoreovirinae* subfamily encompasses six genera, *Cordoreovirus*, *Mimoreovirus*, *Orbivirus*, *Phytoreovirus*, *Rotavirus* and *Seadornavirus*. Viruses in genus *Cardoreovirus* infect only crustaceans. Viruses in the single and type species of genus *Mimoreovirus* have 11 segments of dsRNA and infect the unicellular and ubiquitous alga *Micromonas pusilla*. Reoviruses in the genus *Orbivirus* have 10 dsRNA segments and are considered as arboviruses infecting a wide range of vertebrate (mammalian and avian) hosts and their arthropod vectors, like gnats, mosquitoes, phlebotomines and ticks. While orbiviruses infect invertebrate vectors they have little to no effect on the infected arthropod and will not be described in this article. Genus *Rotavirus* viruses have 11 dsRNA segments and infect only vertebrates and are transmitted by the fecal-oral route. *Homalodisca vitrepenis* reovirus, is the only reovirus in genus *Phytoreovirus* that infects only an insect, the glassy-winged sharpshooter and is not found in plants frequented by this pest. While most reoviruses in the genus *Seadornavirus* are considered arboviruses infecting vertebrates and their invertebrate vectors, two viruses Kadipiro virus and Liao Ning virus have so far been found only in mosquitoes. A summary of the recognized species or reoviruses in the *Sedoreovirinae* infecting only invertebrates is provided in Table 7.

Cardoreovirus

The first cardoreovirus (from *carcinus* for crab and *dodeca* for 12 dsRNA segments) was isolated in 2004 from diseased mitten crabs (*Eriocheir sinensis*). The genus has a single species, the type species *Eriocheir sinensis reovirus* with *Eriocheir sinensis reovirus* (ESRV905) as an exemplar virus member. There are at least five other possible members of the genus, *Callinectes sapidus reovirus* from blue crab, *Carcinus mediterraneus reovirus* W2 (CMRV) from shore crab, *Macrobrachium nipponense reovirus* from prawn, *Macropipus depurator reovirus* P from swimming crab and *Scylla serrata reovirus* from mud crab. The cardoreovirus icosahedral virions are about 70 nm in diameter and have a smooth non turreted surface, with an RNA containing core of about 55 nm diameter. All cardoreoviruses, except *Macrobrachium nipponense reovirus* which has 10 dsRNA segments, have a genome of 12 dsRNA segments. Replication occurs in the cytoplasm of crab cells and virions appear as rosettes around viral inclusion bodies.

Vago in 1966 described the first crustacean virus ever to be identified, Paralysis virus of *Macropipus depurator* virus, now known as the cardoreovirus *Macropipus depurator reovirus* P (the "P" stands for paralysis) which causes a slowly developing paralysis and darkening exoskeleton.

Fig. 5 Neighbor-joining phylogenetic tree, built with available polymerase sequences for representative members of 15 recognized genera of family *Reoviridae*. The abbreviations and accession numbers are those provided in [Table 6](#). The scale bar indicates the number of substitutions per site.

Carcinus mediterraneus reovirus W2 (CMRV) isolated from the hepatopancreas of the shore crab infects interstitial cells of the hepatopancreas, midgut, gills and haemocytes.

Infection of blue crabs in crab fisheries on the Atlantic coast of North and South America with *Callinectes sapidus* reovirus leads to mortalities of up to 100% in both wild and farmed populations. Diagnosis of CSRV is by in situ hybridization and RT-PCR.

Eriocheir sinensis reovirus (EsRV905) was first reported in 2004 from freshwater crab *Eriocheir sinensis*. ESRV is associated with trembling disease, including trembling of the legs, sluggishness and loss of appetite, in farmed mitten crabs in China. This is an economically important disease of freshwater cultured Chinese mitten crabs in Jiangsu Province. The virus infects connective tissue of the gills, midgut, hepatopancreas and hemocytes with mortality reaching 30% in experimental infections. The ESRV WX-2012 genome has an aggregate size of 23,913 bp with a G + C content of 43.80% and the 12 dsRNA segments range from 1.18 to 4.24 kb in size. Genome segment 1 encodes the RdRp of 1217 aa.

Scylla serrata reovirus, originally named mud crab reovirus, was first isolated from mud crab in southern China in 2007. It causes sleeping disease, a severe disease in marine-cultured mud crab in southern China. The highly pathogenic virus infects connective tissues of the hepatopancreas, gills and intestines with mortality reaching 70% in affected farms. Clinical signs include lethargy, anorexia and a gray discoloration. The virus causes vacuolar degeneration of connective tissues in the heart, stomach and intestines. During infection the presence of high numbers of virions results in crystal-like inclusion bodies in the cytoplasm. The *Scylla serrata* reovirus dsRNA genome has an aggregate size of 24,464 bp with 12 segments ranging in size from 1.16 to 4.33 kb.

Macrobrachium nipponense reovirus, was first described in 2016 in farmed freshwater prawn (oriental river prawn) *Macrobrachium nipponense*. Though there are no clinical signs of infection the virus can be associated with smaller shrimp and high levels of mortality.

^aAlthough a phytoreovirus, *Homalodisca vitripennis reovirus* has been detected solely in the glassy winged sharpshooter, it has not been detected in any plants (e.g. citrus trees) where the insect is commonly found. Other phytoreoviruses are known to be plant viruses vectored by invertebrates.

^bWhile considered arboviruses replicating in vertebrate hosts and their invertebrate vectors, the *Seadornavirus* Kadipiro virus has been isolated solely from mosquitoes.

Phytoreovirus

Phytoreoviruses (from “phyto” Greek for plant) were initially discovered in 1941 as wound tumor viruses of plants transmitted by leaf hoppers in which the virus also replicates. The phytoreovirus icosahedral virions appear to be double shelled with a diameter of about 70 nm diameter. While phytoreoviruses are generally considered as plant viruses vectored by cicadellid leafhoppers, they induce no marked disease in the leafhopper vector. However, one unclassified reovirus, *Homalodisca vitripennis reovirus* (HoVRV) in the genus *Phytoreovirus* appears to have only an insect host, the hemipteran glassy winged sharpshooter. This virus was first described in 2009 and found to be closely related to Rice dwarf virus. It appears to be maintained in the absence of a plant host. The genome of *Homalodisca vitripennis reovirus* has an aggregate size of 25,724 bp with a G + C content of 38.70% and the 12 ds RNA segments range in size from 1.04 to 4.47 kb.

Seadornavirus

The Banna virus, in the genus *Seadornavirus* (from Southeast Asian dodeca for 12 dsRNA segments), was first discovered in 1987 in a patient with encephalitis and fever in China and is an arbovirus transmitted by *Anopheles* and *Culex* mosquitoes. However, two seadornaviruses have been found only in mosquitoes, Kadipiro virus in *Culex* and Liao ning virus in *Aedes dorsalis*. Seadornavirus icosahedral virions have a well-defined dual shell surface capsomeric structure with a diameter of 60–70 nm and a 40–50 nm core. Kadipiro virus was first discovered following growth in mosquito C6/36 cells of material collected from *Culex fusccephalus* from Java, Indonesia in 1981. Since then it has been isolated from other mosquitoes, particularly from China. The Kadipiro virus

genome has an aggregate size of 20,985 bp with a G + C content of 37.68% and the 12 dsRNA segments range in size from 0.77 to 3.77 kb. Liao ning virus, another seadornavirus, was initially isolated from *Aedes dorsalis* mosquitoes in North East China in 1997. The Liao ning virus genome has an aggregate size of 20,739 bp with a G + C content of 41.36% and the 12 dsRNA segments range in size from 0.76 to 3.74 kb.

Rhabdoviruses of Insects (*Rhabdoviridae*)

Andrea González-González, Nicole T de Stefano, David A Rosenbaum, and Marta L Wayne, University of Florida, Gainesville, FL, United States

© 2021 Elsevier Ltd. All rights reserved.

Classification

Rhabdoviruses are negative sense, single stranded RNA viruses that infect a wide range of hosts including mammals, birds, fish, reptiles, plants, and arthropods, and have a considerable impact on crop production and public health. The family *Rhabdoviridae* belongs to the order *Mononegavirales* and is classified as a member of group V from the Baltimore system based on its method of mRNA synthesis. The *Rhabdoviridae* are composed of 20 genera and 144 defined species as well as many unclassified isolates. Each genus corresponds to a monophyletic group in a phylogenetic reconstruction inferred using a maximum likelihood algorithm and the full-length sequence of the large L gene. The L gene is a reliable molecular marker for taxonomic classification due both to its low rate of recombination and because its high level of conservation, with some regions involved in functions such as transcription and replication. Besides sharing a common evolutionary history, members of each genus have similar genomic structure, transmission mode and host range.

Insect rhabdoviruses can be divided into two groups: one whose members infect vertebrate hosts through arthropod vectors (i.e., arboviruses), and one whose members infect solely insects. Members of the genera *Curiovirus*, *Ephemerovirus*, *Hapavirus*, *Ledantavirus*, *Sripuvirus*, *Tibrovirus*, *Vesiculovirus* and *Caligrhavirus* have been isolated from arthropod vectors and can also infect vertebrate hosts. In contrast, the genera *Almendravirus* and *Sigmavirus* comprise viruses capable of infecting only arthropods. A phylogenetic analysis using the conserved regions of the L protein led to the suggestion of new genera tentatively called *Bahivavirus* and *Sawgravivirus* (not yet approved by ICTV) from arthropod hosts; it is not yet known whether they can infect non-arthropod hosts.

Additional novel rhabdoviruses have been identified in insect hosts using next-generation sequencing technologies. Some of these are still in the process of being classified into particular genera, such as the Withyham and Lye Green viruses isolated from *Drosophila obscura*, Merida virus isolated from mosquitoes (MERDV), Apis rhabdovirus-1 (ARV-1) and Apis rhabdovirus-2 (ARV-2) isolated from bees, bumble bees and their mites. Again, the breadth of host range for these viruses remains to be determined.

Almendravirus and *Sigmavirus* are the largest genera whose members infect only insects. So far, five different species are officially classified as *Almendravirus* and seven as *Sigmavirus* (Table 1). The *Almendravirus* species are isolated from mosquitoes in the Americas and the *Sigmavirus* species from different species of flies collected around the world (Spain, USA, Kenya, France, Ghana and the UK). Recent metatranscriptomic studies have suggested the existence of more *sigmavirus* species (Table 1) that remain unclassified.

Table 1 Member species of invertebrate Rhabdoviruses^a

Genus	Species	Virus name abbreviation	Host
<i>Sigmavirus</i>	<i>Drosophila affinis sigmavirus</i>	DAffSV	Fruit fly

^aTable elaborated using information from Longdon *et al.* (2015), Walker *et al.* (2018) and from the ICTV Taxonomy Report at: https://talk.ictvonline.org/ictv-reports/ictv_online_report/negative-sense-rna-viruses/mononegavirales/w/rhabdoviridae.

^bNewly discovered, unclassified *Sigmavirus* species. Membership in the *Sigmavirus* genus is implied by isolation from CO₂ sensitive flies using RNA-Seq.

Virion Structure

As other members of the family *Rhabdoviridae*, virions from the *Sigmavirus* and *Almendraviruses* genera are bullet shaped and enveloped. Sigmavirus particles have an approximate diameter of 80 nm and a length of 100 nm, while Almendraviruses particles have a 40–55 nm diameter and 190–460 nm length. The outer surface of the virions have spikes made by glycoprotein that cross the lipidic envelope. The inside of the virion is composed of the nucleocapsid consisting of one single molecule of negative sense single-stranded RNA attached to a nucleoprotein, RNA-dependent RNA polymerase and a phosphoprotein. In addition there is also a matrix protein that links the nucleocapsid to the membrane glycoproteins.

Genome

Rhabdoviruses have negative sense, single stranded, unipartite RNA genomes 11–16 kb length consisting of five canonical structural genes that encode (3′–5′) the nucleoprotein (N), phosphoprotein (P), matrix protein (M), glycoprotein (G) and large protein (L) (Fig. 1). The nucleoprotein constitutes the major component of the viral nucleocapsid and binds the template bases to the polymerase. The phosphoprotein interacts physically with L ensuring it is properly placed on the N-RNA template. It also secures the correct synthesis of N. The matrix protein confers the inner structural component of the virion and is thought to regulate genomic RNA transcription. The glycoprotein binds to host cell receptors and induces endocytosis of the virus. The large protein is a component of the nucleocapsid. It is involved in functions related to transcription and replication, like RNA-dependent RNA polymerase (RdRp) 5′ capping and 3′ polyadenylating. Each gene is separated by short untranscribed intergenic sequences and has conserved transcription stop and start sequences of about 10 nt in length. The genome of some rhabdoviruses

Fig. 1 Genome organization of different insect rhabdoviruses. In contrast to the typical rhabdovirus genome structure consisting on N, P, M, G and L ORFs, the typical *Sigmavirus* genomes encode the X protein whose function is unknown. *Drosophila busckii* sigmavirus encodes an extra protein between G and L with unknown function as well. Almendraviruses genomes do not code for the X protein but encode a class 1a viroporin-like protein ORF which is located between G and L (filled rectangle). Empty spaces between ORFs corresponds to untranscribed intergenic sequence regions. The broken line indicates genome regions not sequenced. Modified from Dietzgen, R.G., Kondo, H., Goodin, M.M., Kurath, G., Vasilakis, N., 2017. The family Rhabdoviridae: Mono- and bipartite negative-sense RNA viruses with diverse genome organization and common evolutionary origins. *Virus Research* 227, 158–170. Longdon, B., Murray, G.G.R., Palmer, W.J., *et al.*, 2015. The evolution, diversity, and host associations of rhabdoviruses. *Virus evolution* 1, 1–12. Walker, P.J., Blasdel, K.R., Calisher, C.H., *et al.*, 2018. ICTV Virus Taxonomy Profile: Rhabdoviridae. *Journal of General Virology* 99, 447–448.

includes additional genes located between the structural proteins, therefore genomes of viruses from different genera may vary in length and organization.

Sigmavirus Genome

Members of the *Sigmavirus* genus have genomes that range from 12.4 to 14.5 kb and typically encode six proteins. The N, P, M, G and L proteins have the same structural characteristics and are homologous to proteins of other rhabdoviruses. The X gene is located between P and M, and codes for the protein PP3 (also called X protein) which is presumably involved in host-virus interactions. Different genome sizes are explained by the variation in length of the untranscribed intergenic sequences. For example, there is a 664 nucleotide untranscribed region between G and L in the G *Drosophila affinis sigmavirus* (DAffSV) (Fig. 1).

Some of the newly discovered related and unclassified sigmaviruses isolated from different species of flies share the canonical genome structure of six genes present in *Drosophila melanogaster sigmavirus* (DMelSV) while others deviate from the prototypic genome organization. For example, the *Drosophila busckii* sigmavirus (DBusSV) genome does not code for the X gene however, it has an accessory ORF of unknown function between the G and L genes. Pararge aegeria rhabdovirus (PAerRV) does not code for the X protein, and the G protein is split into two contiguous ORFs. Other sigmaviruses have been identified from RNAseq data including *Drosophila montana* sigmavirus (DMonSV), *Drosophila sturtevantii* sigmavirus (DStuSV) and *Scaptodrosophila deflexa* sigmavirus (SDefSV); however, their genomes are not yet fully sequenced (Fig. 1).

Almendravirus Genome

Members of the *Almendravirus* genus have genomes that range from 10.5 to 11.5 kb. They also encode the canonical five proteins present in genomes of members of the *Rhabdoviridae* family, with the same structural characteristics and homology of the proteins of other rhabdoviruses. However, *Almendravirus* encode an additional class 1a viroporin-like protein as an independent transcriptional unit between the G and L genes. The Balsa virus (BALV) genome, has an extra ORF (Px) within the P gene which function is unknown (Fig. 1).

Other Insect Rhabdovirus Genomes

The recently discovered *Apis mellifera* Rhabdoviruses 1 (ARV-1) and 2 (ARV-2) have genomes ~14.5 kb long. They both have the prototypic rhabdovirus genome structure consisting of the five open reading frames N, P, M, G and L. In contrast, the genome of other unclassified rhabdoviruses, isolated from bedbugs (Shuangao Bedbug Virus 2), mosquitoes (Wuhan Mosquito Virus 9) and flies (Shayang Fly virus 3), codes only for the G and L proteins plus three different capsid proteins (VP1, VP2 and VP3).

Life Cycle

Sigma virus has the same basic steps as other members of other rhabdoviruses for cell entry, transcription, translation, replication, and assembly, all of which occur predominately in the cytoplasm. Rhabdoviruses have five essential proteins that aid in these processes: nucleoprotein (N), glycoprotein (G), RNA-dependent RNA polymerase large subunit (L), phosphoprotein (P), and matrix protein (M). Initially, the G protein aids in the attachment of the virus to the host cell membrane. Entry of the virus into the host cell occurs by receptor mediated endocytosis, utilizing clathrin coated pits. The low pH levels in the environment facilitate fusion of the viral envelope and the host cell membrane by causing a conformational change of the G protein which subsequently releases the nucleocapsid into the cytoplasm where the virus can undergo transcription.

Transcription of the viral RNA is initiated by the detachment of the M protein from the nucleocapsid. Primary transcription of the negative-sense RNA is catalyzed by the viral transcriptase enzyme and follows a stop-start pattern starting at the 3' end of the RNA. Each mRNA transcript has an initiation sequence and is terminated by a polyadenylation signal, a string of A's at the end of the sequence. The essential genes are transcribed as capped poly-adenylated mRNAs in the order N → P → M → G → L. Small RNAs are also produced that are uncapped and positive sense, typically considered leader RNAs. Once transcribed, the mRNA sequences are translated into proteins and these proteins are transported to varying areas of the cell. Protein translation of N, M, P, and L occur in cytoplasmic polysomes. However, in the case of the G protein, it is translated on membrane-bound polysomes, and then transported from the endoplasmic reticulum to the Golgi apparatus for processing and finally to the plasma membrane.

After a sufficient amount of protein is produced, genome replication is initiated. This focuses mainly on viral encapsidation, where proteins N and P are vital components in this process. The synthesized positive sense antigenome provides a template for formation of the negative sense RNA to be encapsidated. Once initial RNA replication occurs, secondary transcription, translation, and replication can take place. After formation of the nucleocapsid, it attaches to the cell membrane and the synthesized M protein aids in the budding process where virions are released and are able to proliferate the infection to adjacent cells.

Integration Into the Host Genome

SIGMAV-like and other rhabdovirus-like elements homologous to genes coding for protein L (RNA-dependent RNA polymerase), N (Nucleoprotein), P (polymerase-associated protein) and G (glycoprotein) are integrated into the genomes of a range of different *Drosophila* species as well as the genomes of the mosquito *Aedes aegypti* and tick *Ixodes scapularis*. There is evidence that suggests that the sequence encoding the viral protein P was integrated into the *D. yakuba* genome by retrotransposon template-switching, and that it is expressed by the host.

Epidemiology

Distribution, Spatial and Temporal

Rhabdoviruses have been found in worldwide distributed natural populations of insects from the Drosophilidae, Tephritidae, Nymphalidae, Culicidae and, Apidae families.

Transmission

The most studied rhabdovirus in insects is sigma virus, which has been isolated from different *Drosophila* species ([Table 1](#)). DmelSV (sigma virus isolated from *D. melanogaster*), DAffSV (sigma virus isolated from *D. affinis*) and DObsSV (sigma virus isolated from *D. obscura*) are vertically transmitted by both parents to their offspring, a condition thought to ensure the persistence of vertically transmitted virus in natural populations despite the fitness cost such viruses can impose on infected flies.

In the wild, transmission efficiency of DmelSV and DAffSV by females is higher compared to males. In contrast, DObsSV is transmitted at similar rates by both parental sexes. Additionally, if a fly is infected by its female parent, the probability of transmitting DmelSV to its offspring is higher than when it is infected by its male parent meaning that while there can be patrilineal transmission for multiple generations, the transmission efficiency decreases with each generation. In contrast, *D. affinis* and *D. obscura* males infected by their male parents do not transmit the virus to their offspring. Conveniently, although sigma virus is vertically transmitted in nature, sigma virus can be experimentally injected into naïve female flies where it can replicate and be transmitted to the next generation by these flies.

Prevalence

D. melanogaster females tend to have slightly higher prevalence of sigma virus than males in the field and this prevalence varies from season to season in natural populations ranging from 28% to 6.2% depending on the year. This prevalence may be influenced by a latitudinal or climatic gradient (lower latitudes having higher prevalence compared to higher altitudes). In *D. obscura*, the presence of DObsSV ranges from 22% to 73% depending on the collecting site in the UK.

Laboratory experiments have demonstrated that DmelSV, DAffSV and DObsSV can persist and replicate in closely related novel hosts.

Population Dynamics

Sigma virus isolated from different natural populations of *D. melanogaster* across Europe shows almost null genetic diversity and zero levels of recombination. At the same time, this diversity is structured since viral isolates from a particular population share a unique pool of genetic variants compared to other populations. Like DmelSV, DObsSV has very low genetic variation. However, in DObsSV these genetic variants are distributed homogeneously among different geographical populations. Using mathematical modeling, it has been demonstrated that DObsSV invades natural populations of *D. obscura* flies at a fast pace, dramatically increasing its population size. At the single fly level, infections by multiple strains of DmelSV have been reported by measuring their plaque size and incubation times to CO₂ sensitivity. Sequence variation consistent with multiple infections has also been detected.

Clinical Features

Infection with sigma virus decreases female fecundity in natural populations of *D. melanogaster*. Also, eggs laid by uninfected females had greater viability and faster developing times than those laid by infected females in laboratory population.

Pathogenesis

The paralysis experienced by *D. melanogaster* flies after being exposed to CO₂ has been attributed to the damage caused to the nervous tissue by the replication of sigma virus in the fly thoracic ganglia. It also infects other tissues like the eyes, brain and other

nerves. However, the exact mechanism remains unknown. Although not directly studied in the *D. melanogaster*-sigma virus system, it can be hypothesized that the protein G plays an important role in this CO₂ sensitivity. In other members of the Rhabdovirus family such as rabies, the viral protein G attaches to different host cell receptors, allowing the entrance of the virus into nervous cells and mediates the spread of the virus among neurons.

Diagnosis

Sigma virus-infected flies die or become permanently paralyzed after being exposed to high levels of CO₂ and this CO₂ sensitivity is correlated with the viral titers. This symptom is commonly used to screen flies in natural and laboratory populations. Adult flies are exposed to CO₂ for 5–15 min at 12°C and after 30 min, infected flies rarely recover. While death after exposure with CO₂ is very strongly associated with sigma virus infection in *D. melanogaster*, in other *Drosophila* species like *D. obscura*, some infected flies are not sensitive to CO₂. Another way to test for sigma virus presence is by quantitative real-time PCR (qRT-PCR) or by first-strand synthesis followed by quantitative PCR.

Sarothroviruses (*Sarothroviridae*)

Azeez Sait Sahul Hameed, C. Abdul Hakeem College, Melvisharam, India

© 2021 Elsevier Ltd. All rights reserved.

Glossary

Cell line It is a permanently established cell culture that will proliferate indefinitely in appropriate cell culture medium.

Pathogenicity Ability of infectious agent to cause disease.

Post-larvae One of early developmental stages in freshwater prawn after larval stages.

Satellite virus Virus dependent on another virus for replication and transcription.

Vertical transmission Transmission of virus from an infected brooder to its progeny.

Introduction

The giant freshwater prawn, *Macrobrachium rosenbergii* is the most favored crustacean species by the prawn farmers and is being cultured on a large-scale in many countries. Disease is one of the important factors which limit the aquaculture production worldwide. Like other animals, prawns are affected by viruses, bacteria, fungi, and metazoan parasites. Very few diseases have been reported in freshwater prawn when compared to marine shrimp because *M. rosenbergii* is a moderately disease-resistant species. Among the pathogens, prawn viruses are very important and responsible for huge economic losses, particularly in the hatchery and nursery phases. Reported prawn viruses include *Macrobrachium* hepatopancreatic parvo-like virus (MHPV), *Macrobrachium* muscle virus (MMV), infectious hypodermal and hematopoietic necrosis virus (IHHNV) and white spot syndrome virus (WSSV). MHPV, MMV, and IHHNV have been reported only once in freshwater prawn (Anderson *et al.*, 1990; Tung *et al.*, 1999; Hsieh *et al.*, 2006). *M. rosenbergii* is not a natural host of WSSV, but the syndrome was experimentally induced in this species via different routes of infection. A new viral disease namely white tail disease caused by *Macrobrachium rosenbergii* nodavirus and *Macrobrachium* satellite virus 1 was reported to cause severe mortality in freshwater prawn hatcheries and nursery ponds in different parts of world.

Geographical Distribution

This virus was first reported in the French West Indies later in China, Chinese Taipei, Thailand, Australia, and Malaysia. The occurrence of WTD is being reported in other prawn growing countries.

Clinical Signs of WTD and Histopathology

The clinical signs of WTD in infected post-larvae include lethargy and opaqueness of the abdominal muscle that gradually extends from the center to the anterior and the posterior sections of the muscle. Degeneration of the telson and uropods is observed in severe cases. The prevalence of opaque and milky post-larvae increases dramatically 1–2 days later and changes are particularly obvious in the abdomen (tail). The mortality rate reaches a maximum at five days after the first observation of gross signs. The most affected tissues in WTD-infected post-larvae are striated muscles in the abdomen and cephalothorax and the connective tissues of all organs. There are basophilic cytoplasmic inclusions with a diameter of 1–40 µm in striated muscles of the abdomen, cephalothorax, and intratubular connective tissue of the hepatopancreas. No viral inclusions were observed in epithelial cells of the hepatopancreatic tubules or in midgut mucosal epithelial cells. Muscles exhibit multifocal areas of hyaline necrosis of the fibers, with moderate edema.

Morphology of Virus

Extra small virus particles are non-enveloped, icosahedral and about 15 nm in diameter with a density in CsCl of 1.325 g/ml and serologically unrelated to those of *Macrobrachium rosenbergii* nodavirus (Fig. 1). Two overlapping coat proteins of about 17 kDa (CP-17) and 16 kDa (CP-16) are found in extra small virus particles. Since the particles are very small, this viral agent has been called extra small virus (XSV).

Genome Organization

The genome of XSV is a linear positive-sense RNA molecule and contains 796 nucleotides with a single ORF located between nucleotides 63 and 587, and a short poly (A) tail of 15–20 nucleotides at the 3'-end. A potential polyadenylation signal (AAUAAA)

Fig. 1 Negatively stained purified (a) extra small virus (bar = 50 nm) and (b) *Macrobrachium rosenbergii* nodavirus (bar = 100 nm).

is located 6 nt upstream of the poly(A). The ORF encodes two capsid proteins namely CP16 and CP17 (**Fig. 2**). Amino acid sequence analysis indicates that CP16 is synthesized by internal initiation at a second methionine codon 11 amino acid codons downstream of the first initiation codon. The two forms of the capsid protein are synthesized in an equimolar ratio.

Taxonomic Position

The genome sequence of XSV does not have any significant homology with known virus genomes. The genome of XSV encodes only the capsid proteins and this virus depends on the RdRp of MrNV for replication and transcription. This virus meets the primary conditions of satellite viruses and appears more similar to the known satellite viruses infecting plants (e.g., tobacco necrosis satellite virus-like) than those infecting insects (e.g., chronic bee paralysis-associated satellite virus). XSV is a virus member of the single species, *Macrobrachium satellite virus 1* in the single genus, *Macronovirus* belonging to the family *Sarothroviridae*. Isolates from different geographical locations, including French West Indies, Thailand, Taiwan, China and India, have been reported. All isolates belong to different geographical locations showed 96%–99% nucleotide sequence identity in their capsid protein genes but the encoded proteins are not recognizably similar to proteins in the public sequence databases.

Pathogenicity and Transmission of Disease

Mixtures of both MrNV nodavirus and XSV sarothroviruses caused 100% mortality in post-larvae 12 days post infection (d p.i.) by immersion and the results indicate the possibility of horizontal transmission of disease. In the virus-infected group, post-larvae started showing whitish muscles at 7 d p.i. and reached the highest proportion at 12 d p.i. MrNV and XSV were purified and post-larvae were challenged with different combinations of these two viruses by immersion ([Zhang et al., 2006](#)). Clinical signs of WTD and high mortality were observed in post-larvae challenged with combinations containing a relatively high proportion of MrNV and low proportion of XSV. In contrast, there was little sign of WTD and low mortality in post-larvae challenged with a higher proportion of

Fig. 2 Genome organization of MrNV and XSV (*Sarothroviridae*). RdRP: RNA-dependent RNA polymerase, CP: capsid protein. Numbers indicate nucleotide positions.

XSV than MrNV, indicating that MrNV plays a key role in causing disease in *M. rosenbergii*. RT-PCR analysis confirmed the presence of both viruses in experimentally infected post-larvae and in gill tissue, head muscle, stomach, intestine, heart, hemolymph, pleopods, ovaries, and tail muscles of experimentally injected adult prawns. Previous studies revealed that MrNV and XSV viruses were always found to be associated with WTD (Zhang *et al.*, 2006). Despite these studies, the role played by XSV in the disease and particularly in its pathogenicity remains unclear and needs further research. Experimental studies confirmed vertical transmission from infected broodstock to post-larvae.

XSV affects mainly post-larvae of *M. rosenbergii* and is responsible for severe mortalities in the early life stages of freshwater prawn. The vertical mode is the main route of WTD transmission. Experimental infection of brooders with both MrNV and XSV indicated that the vertical route is the main route of disease transmission. In the infected brooders, ovarian tissue and fertilized eggs were found to be positive for MrNV/XSV as evidenced by RT-PCR and mortality of up to 100% was observed in post-larvae hatched from eggs of infected brooders. Some virus-infected post-larvae can survive to adulthood and can act as carriers of the disease. *Artemia* which plays an important role in nutrition of shellfish at the larval stages, may also serve as a vector for MrNV/XSV. The results of experimental infection and RT-PCR assay revealed that both MrNV and XSV responsible for WTD, are possibly transmitted to post-larvae of freshwater prawn via the oral route.

Host Range

The early life stages such as larvae, post-larvae and early juvenile of *M. rosenbergii* were found to be susceptible to XSV. No mortality was observed either in naturally or experimentally (MrNV/XSV) infected subadult and adult prawns. In addition, the PCR results showed XSV-positive in kuruma prawn (*Penaeus japonicus*), Indian white prawn (*Penaeus indicus*), giant tiger prawn (*Penaeus monodon*), dragonfly (*Aeshna* sp.), giant water bug (*Belostoma* sp.), beetle (*Cybister* sp.), backswimmer (*Notonecta* sp.), hairy river prawn (*Macrobrachium rude*), monsoon river prawn (*Macrobrachium malcolmsonii*), brine shrimps (*Artemia* sp.), and red claw crayfish (*Cherax quadricarinatus*).

Susceptibility of Cell Line to XSV

XSV can be easily propagated in the C6/36 mosquito *Aedes albopictus* cell line. This cell line can be cultured in Leibovitz L-15 medium containing 100 International Units ml⁻¹ penicillin, 100 µg ml⁻¹ streptomycin and 2.5 µg ml⁻¹ fungizone supplemented with 10% fetal bovine serum at 28°C. The C6/36 cell line was found to be useful for propagation of XSV and viral replication was confirmed by RT-PCR, acridine orange staining, infectivity studies and electron microscopy. A specific cytopathic effect was not observed in XSV-infected cell lines, but multiple vacuolations were observed.

Diagnostic Tools

XSV can be detected by genome-based and protein-based methods. Various diagnostic methods including histopathology have been developed in different laboratories throughout the world to detect XSV. Other methods include immunological methods, RT-PCR, loop-mediated isothermal amplification (LAMP), in-situ hybridization, and dot blot hybridization. All the above works were aimed at detecting MrNV and XSV in the samples.

Control Measures

RT-PCR and other user-friendly kits for detection of XSV are available for commercial use. Therefore, broodstock and seed screening are strongly recommended to prevent WTD in the farms. Broodstock or seed that test positive for WTD are recommended to be discarded by proper zoo-sanitary methods. Usual sanitation and control protocols for viral infections are recommended to avoid WTD in the prawn farm.

Glossary

Biological Control (= biocontrol) A method to control insect pests using organisms that are natural predators, parasites, or pathogens.

Biopesticide (= biological pesticide) A pesticide whose active ingredient is biologically based, including predators, parasites, or pathogens.

Entomopathogen A pathogen of insects.

Ribosomal Frameshifting Method of translation exhibited by some viruses to fuse proteins encoded by two overlapping open reading frames.

Trophallaxis In social insects, the exchange of food or other nutrients between colony members by mouth-to-mouth or mouth-to-anus feeding.

Introduction

Soliniviridae is a new family of viruses that possess non-segmented, single-stranded, positive-sense RNA genomes of 10–11 kilobases. This is a highly divergent group exhibiting phylogenetic, genome, and replication characteristics with aspects that are both picornavirus- and calicivirus-like. Among the two classified species of the family, gene order appears conserved. However, whereas the genome of *Nylanderia fulva* virus 1 (NfV-1) contains a single large open reading frame, in the genome of *Solenopsis invicta* virus 3 (SINV-3) this is split into two large open reading frames with the second open reading frame being accessed by a ribosomal frameshifting mechanism, resulting in the translation of a trans-frame fusion polyprotein. In both species, the non-structural proteins involved in replication (picorna-like helicase, protease and RNA-dependent RNA polymerase) are encoded towards the 5' end of the genome, and the capsid proteins (a jelly-roll fold domain, an extension domain, and an additional capsid-associated protein) are encoded towards the 3' end. The capsid proteins may be expressed from genomic or subgenomic RNAs. SINV-3 is the best characterized of the two species and infects the invasive red imported fire ant (*Solenopsis invicta* Buren); NfV-1 infects the tawny crazy ant (*Nylanderia fulva* (Mayr)). Although SINV-3 and NfV-1 infect ant species (Insecta: Formicidae), additional unclassified related sequences have been identified in various other arthropods.

Classification (Compact)

The *Soliniviridae* name is derived from the type species, *Solenopsis invicta* virus 3. The family currently comprises two genera, each currently containing a single species, *Invictavirus* (derived from *Solenopsis invicta* virus 3) and *Nyfulvavirus* (derived from *Nylanderia fulva* virus 1). Comparative analyses of protein complement, gene expression, and genome organization of the two members suggest that the family may form a sister group to the *Caliciviridae*. However, this conclusion will require additional sequence discoveries and analyses of related viruses to resolve the taxonomic position of the group.

The *Soliniviridae* exhibit characteristics that are picornavirus-like and calicivirus-like. Similar to both picornaviruses and caliciviruses, the *Soliniviridae* encode a superfamily III helicase, a 3C-like chymotrypsin-related cysteine protease and a superfamily I RNA-dependent RNA polymerase. Additional calicivirus-like characteristics exhibited by soliniviruses include a single jelly-roll fold capsid domain, capsid protein encoding in the 3' end of the genome, production of a capsid-encoding subgenomic RNA (empirically established in SINV-3 only), similar nucleotide sequences at or near the genomic and subgenomic RNA 5'-termini, and the presence of a capsid projection domain. Another calicivirus characteristic exhibited by SINV-3 is its environmental stability and resistance to heat inactivation. SINV-3 remains viable for years within ant corpses.

Currently, the genomes of three SINV-3 isolates have been sequenced in entirety, including the DM isolate from North American *Solenopsis invicta* (GenBank Accession FJ528584), the SF isolate from South American *Solenopsis invicta* (GU017972), and the Hybrid isolate from *Solenopsis invicta* x *richteri* hybrid ants (MF797911). The isolates exhibit highly similar amino acid sequences (>98% identical) with the majority of nucleotide differences being synonymous. The genome of NfV-1 (isolate Florida initial) has also been sequenced in entirety (KX024775).

Virion Structure

Electron microscopy of SINV-3 revealed spherical particles with irregularly spaced surface projections, cup-shaped depressions, and a diameter of 27.3 ± 1.3 nm (Fig. 1). NfV-1 particles were also spherical with irregularly spaced projections, and a diameter of 28.7 ± 1.1 nm. This morphology was also reported in related unclassified viruses, including Kelp fly virus and *Riptortus pedestris* virus 1. The irregularly spaced surface projections appear to originate at the five-fold axes of symmetry in Kelp fly virus.

Fig. 1 Electron micrographs of a negative stain of a *Solenopsis invicta* virus 3 preparation purified by cesium chloride isopycnic centrifugation. Surface projections (Sp) and cup-shaped depressions (Csd) are evident. Bar size represents 25 nm and 200 nm in the upper and lower panels, respectively.

SINV-3 virions contain two major proteins, viral protein 1 (VP1) and VP1 fused to the capsid projection domain (VP1-CPD) (**Fig. 2**). VP1 is a single jelly-roll capsid protein and is the major component of the virion; particles are presumed to contain 180 copies of VP1 in a $T = 3$ icosahedral shell arrangement. The capsid projection domains of VP1-CPD proteins are thought to form the irregularly spaced projections. The VP1: VP1-CPD ratio is estimated at approximately 5:1 in SINV-3. A third protein, viral protein 2 (VP2) encoded downstream of CPD is detected at only sub-stoichiometric levels in SINV-3 virions. It is presumed that VP2 is proteolytically cleaved from the CPD region but this has not been determined empirically. VP2 is detected at very low levels, and its function or contribution to the virion structure or its formation are not yet known.

For NfV-1, the virion proteins may be slightly different because the genome contains only one long open reading frame. In contrast to SINV-3, no frameshift separates the VP1 and CPD coding sequences (**Fig. 2**) and it is presumed that all VP1 and CPD polypeptides are produced as the single linked form (VP1-CPD). It is possible that this VP1-CPD polypeptide might be subsequently cleaved to produce free VP1. This latter notion is supported by evidence from the related, unclassified Kelp fly virus whose genome, like that of NfV-1, also contains only a single open reading frame. Two proteins were identified in virions of Kelp fly virus in a molar ratio of 5:1. These proteins may correspond to VP1 and VP1-CPD, respectively.

Genome

Members of the family *Soliniviridae* have single-stranded, positive-sense RNA genomes of 10–11 kb with polyadenylated 3' tails. The genome of NfV-1 contains a single large open reading frame. Conversely, the genome of SINV-3 contains a large 5'-proximal open reading frame (spanning approximately $\frac{3}{4}$ of the genome), and a second smaller 3'-proximal open reading frame accessed via a -1 ribosomal frameshift at the 3' terminus of open reading frame 1. Thus, open reading frame 1 can be translated alone, or in conjunction with open reading frame 2 as a trans-frame fusion polyprotein.

Regardless of species, the protein order is similar. ORFs for structural proteins follow the non-structural proteins. Superfamily III helicase, 3C-like chymotrypsin-related protease and superfamily I RNA-dependent RNA polymerase domains are encoded towards the 5' end and followed by a jelly-roll fold domain (VP1), the capsid projection domain (CPD), and the additional capsid-associated protein (VP2) towards the 3' end. Although not confirmed empirically, a viral protein of the genome (VPg) is thought to be encoded upstream of the 3C-like protease and covalently attached to the 5' end of the genome. A predicted dsRNA binding domain with homology to the 1A suppressor of silencing protein of the dicistrovirus, *Drosophila C virus*, and perhaps acting as a viral suppressor of RNA interference, is encoded between the RNA-dependent RNA polymerase and

Fig. 2 Genome organization of *Solenopsis invicta* virus 3 (*Invictavirus*) and *Nylanderia fulva* virus 1 (*Nyfulvavirus*). Predicted protein domains and their relative positions for the genomic and subgenomic RNA include Helicase (Hel), Protease (Pro), RNA dependent RNA polymerase (RdRP), Jelly-roll capsid viral protein 1 (VP1), Capsid projection domain (CPD), Viral protein 2 (VP2), dsRNA binding protein (*), and Ovarian tumor domain (OTU).

jelly-roll fold domains in both SINV-3 and NfV-1. NfV-1 also encodes a predicted Ovarian Tumor (OTU) domain upstream of the helicase.

In SINV-3, and presumably NfV-1, the capsid proteins may be expressed from both genomic and subgenomic RNAs, which is a calicivirus-like characteristic. A 24 nucleotide perfect repeat (AAAGUCCAGUAAGGUUACUGGCAU) occurs in the untranslated region at the 5' terminus (genome position 18–41) and just upstream of the sequence encoding the dsRNA binding domain (genome position 6664–6687) in SINV-3. This sequence repeat may be a promoter sequence for genomic and subgenomic RNA production. Indeed, the 36 nucleotide sequence at genome position 6652 through 6687 exhibits strong similarity with the sequence of the 5'-terminal 41 nucleotides of the genome. Thus, the start position for the subgenomic RNA likely occurs at genome position 6652, with translation starting at the AUG at genome position 6800–6802. Consistently, northern analysis revealed a subgenomic RNA species of approximately 3800 nucleotides. Based on analogy with the SINV-3 sequence, the potential start site for an NfV-1 subgenomic RNA occurs at genome position 7312 as similar sequence elements (75% identity) are detected at the 5' end of the genome and at the sequence beginning with nucleotide 7312.

Life Cycle

Solinviviruses are thought to follow a replication cycle similar to picorna/caliciviruses. Once the virus gains cell entry it replicates in the cytoplasm and no DNA stage is formed. The viral genome serves a dual purpose as transcript for polyprotein synthesis and template for production of the complementary minus strand (i.e., replicative strand) of the genome, which, in turn, serves as template for production of the infectious plus strand genome. Viral assembly ultimately occurs by encapsidation of a plus strand genome.

SINV-3 and NfV-1 gain entry into the host through the alimentary canal by ingestion. Because the alimentary canal is the primary means of acquiring SINV-3 and NfV-1 infections, virus transmission into their ant hosts is easily accomplished by feeding. After the virus infects an individual ant worker, it is spread intra-colonially by trophallaxis. SINV-3 and NfV-1 exhibit stage-dependent tropism. SINV-3 replication is detected in only adult worker ants. Conversely, the replicative form of NfV-1 appears limited to the larval ant stage.

Epidemiology (Host Specificity/Prevalence/Transmission)

Establishment of host specificity is of paramount importance to establish the suitability for development and ultimate release of an entomopathogen for control purposes. If the entomopathogen (e.g., virus) exhibits broad host specificity, it is possible that non-target insect hosts could be negatively and irreparably impacted.

Host specificity tests have been conducted extensively for SINV-3. Passive and high-dose active exposure of 23 ant species in 14 genera and 4 subfamilies revealed that SINV-3 was capable of replication in only *Solenopsis invicta*, *Solenopsis richteri*, and *Solenopsis invicta* x *richteri* hybrids. Thus, SINV-3 is host specific for ant species within the *saevissima* complex of South American fire ants. Studies also revealed that SINV-3 could not replicate in the honey bee (*Apis mellifera*). The narrow host specificity exhibited by SINV-3 supported intentional release into the *Solenopsis invicta* United States population as a classical biological control agent. Furthermore, SINV-3 was detected naturally occurring in *Solenopsis invicta* ants from several U.S.

states. However, the incidence of SINV-3 was rather low and irregular. Population surveillance studies detected SINV-3 in *Solenopsis invicta* from the native range (Formosa, Argentina), the United States, and parts of the Caribbean. Because the incidence in the United States was low and irregular, intentional releases of SINV-3 have been completed in California and Florida with successful establishment of the virus. Interestingly, SINV-3 exhibits a seasonal phenology. The prevalence of the virus is higher during fall and winter months in Florida. Analysis of the relationship between temperature and prevalence showed a strong negative correlation between SINV-3 presence and warmer temperature. Temperature can have a significant impact on viral replication, assembly, or host resistance.

Based on laboratory studies, SINV-3 transmission occurs through ingestion of virus. Midgut epithelial cells are thought to be the specific target for the virus. After the infection is established in midgut cells the virus spreads to additional tissues by an unknown path. The mode of natural transmission of SINV-3 in *Solenopsis invicta* is not known. However, the virus was successfully transmitted by crickets that had consumed dead, SINV-3-infected ant workers, which had subsequently fallen prey to uninfected *Solenopsis invicta* worker colonies. The transmission was simply mechanical because crickets did not support replication of SINV-3. This mode of transmission facilitates use of SINV-3 as a biopesticide. Indeed, baits have been developed that successfully transmit SINV-3 to fire ant colonies in the laboratory and field.

Perfunctory host specificity tests with NfV-1 suggest that the virus is specific for *Nylanderia fulva* ants. However, more extensive testing will be required to firmly establish the host specificity of the virus.

Clinical Features

Not applicable.

Pathogenesis

The sequelae exhibited by SINV-3 infection of *Solenopsis invicta* begins with a cessation of food retrieval by the worker caste, followed by larval, pupal, and worker mortality and decreased queen fecundity. Very large midden piles composed of brood and worker corpses develop (Fig. 3(A)). Interestingly, in the laboratory the midden piles are created directly on the food source (Fig. 3(B)). SINV-3 titer in moribund worker ants typically exceeds 10^9 SINV-3 genome copies per ant.

Queen weight declines dramatically in the latter stages of SINV-3 infections in fire ant colonies. Decreases in developing ova and reduced fecundity are also associated with infection. It is not known whether the decrease in feeding causes the fecundity/ovary changes observed, or if SINV-3 has a direct impact on the queen. Despite significant larval mortality in colonies infected with SINV-3, the virus does not appear to replicate or assemble in the larval ant stage. Plus-strand SINV-3 is regularly detected in larval stages by RT-PCR, but virus replication or assembly do not appear to occur in this stage. It has been hypothesized that cessation of food retrieval/feeding and/or behavioral changes whereby the workers neglect the developing larvae is the cause of larval mortality. Reduced foraging in response to virus infection has been reported to occur in other arthropod species. NfV-1 is also associated with a decrease in fecundity in *Nylanderia fulva* colonies, although this response occurs inconsistently.

Fig. 3 Large midden pile composed of accumulating corpses from a *Solenopsis invicta* virus 3-infected fire ant colony (A). Often, the midden piles are created on the food source (B). In this case, the food source is the house cricket, *Acheta domesticus*.

Diagnosis (Detection)

Detection of colonies infected with solinviviruses is typically made by molecular analysis of a portion of the genome using RT-PCR or quantitative PCR. In the laboratory, SINV-3 infections may be identified by declining colony health, changes in food consumption and distribution, and increased mortality (midden piles). However, in the field, RT-PCR is required. NfV-1 is best detected by RT-PCR, in the laboratory or field.

Prevention (Biocontrol)

SINV-3 and NfV-1 were discovered using a metagenomics approach coupled with next generation sequencing to detect pathogens within the transcriptomes of pest ant species. The sole purpose of the work was pathogen bioprospecting and discovery. SINV-3 and NfV-1 are being investigated for their use as natural control agents (biological control) against the invasive ant species, *Solenopsis invicta* and *Nylanderia fulva*, respectively. Therefore, from an entomological perspective, introduction and establishment of these viruses into target ant host populations is the objective, rather than disease prevention.

SINV-3 has been released as a classical biological control agent into areas where the virus is not found in *Solenopsis invicta*. In addition, SINV-3 is being developed as a biopesticide. SINV-3-containing baits have been developed and successfully transmit the virus in the laboratory and field. Protein-based baits were superior to sugar- or oil-based baits. The minimum SINV-3 dose required for causing colony collapse was in the 10^7 to 10^9 viral particles per microliter range. Lower doses resulted in a chronic infection with limited impact on colony health. A limitation to commercial development of SINV-3 as a biopesticide is in vitro production of virus. Virus genome production was possible using a baculovirus-driven expression system, but virus assembly failed to occur.

Introduction

Tetraviruses are a diverse group of small, non-enveloped RNA viruses that infect lepidopteran (butterflies and moths) insects. In general, virus particles vary in size from 38 to 41 nm in diameter and share a unique $T = 4$ icosahedral capsid architecture. It is this feature that led to the name “tetravirus”, derived from the Greek *tettares* meaning “four”. Tetravirus particles assemble as procapsids comprising 240 copies of a single capsid precursor protein (CP). During maturation, the CP undergoes autoproteolytic cleavage to form the β (58–67 kDa) and γ (6–8 kDa) subunits of the mature capsid. Tetravirus particles encapsidate one or two single-stranded (ss), positive sense (+ve) genomic RNAs. While some tetraviruses have bipartite genomes, the majority have monopartite genomes ranging from 5.3 to 6.6 kb in size and encoding up to four genes.

The first tetravirus, *Nudaurelia capensis* β virus (N β V), was isolated from diseased South African pine emperor moth (*Nudaurelia cytherea capensis*) larvae in 1968. Structural studies on N β V particles revealed a new type of virus capsid with unusual $T = 4$ icosahedral symmetry that led to N β V becoming the type-member of a new family of viruses then named the *Tetraviridae*. The *Tetraviridae* were classified into two genera according to their genome organization, where viruses with monopartite genomes were classified into the *Betatetraviridae* genus, while viruses with bipartite genomes resided in the *Omegatetraviridae* genus. Comparative analysis of available genome sequences revealed the *Tetraviridae* to be a highly diverse group of viruses, despite the structural conservation of their capsid. Phylogenetic analysis showed that the RNA-dependent RNA polymerase (RdRp) domains of tetravirus replicases can be clustered into three groups, each related to a different supergroup of RNA viral replicases. Consequently, the International Committee for the Taxonomy of Viruses reclassified the *Tetraviridae* into three new families based upon the characteristics of their replicases, namely the *Alphatetraviridae*, the *Permutotetraviridae* and the *Carmotetraviridae* (Table 1). The increasing availability of metatranscriptomic sequence data and the elucidation of the invertebrate virosphere will serve to clarify the viral diversity present in the invertebrates.

Genome Organization

Alphatetraviridae

The *Alphatetraviridae* are classified into two genera according to their genome organization with the *Betatetraviridae* containing virus species with monopartite genomes and viruses with bipartite genomes classified within the *Omegatetraviridae* genus. Currently, there are three omegatetraviruses and seven betatetraviruses species (Table 1). The genome sequence of only one betatetravirus (N β V) is available, so it is possible that other species classified in this genus could in fact be reclassified into the *Permutotetraviridae* or *Carmotetraviridae* families based upon the characteristics of their replicases.

In the omegatetravirus, *Helicoverpa armigera* stunt virus (HaSV), REP is encoded by RNA1, along with three small ORFs, p11, p15 and p8 that overlap with the 3' end of REP (Fig. 1). The HaSV REP (as do those of all sequenced alphatetraviruses) includes the three conserved functional domains, namely methyltransferase (MET), helicase (HEL) and RdRp domain in an N- to C-terminal modular arrangement, characteristic of the alpha-like virus superfamily. The three small ORFs are arranged tandemly and in an in-frame arrangement with p11 and p15 separated by a UGA stop, and UAA GGG separating p15 and p8. These ORFs are translated in HaSV-infected cells via a mechanism that is as yet unknown, but their translation products are thought to be involved in initiating the viral replication complex. The HaSV CP is encoded by the smaller RNA2. At its 5' end, RNA2 encodes a second protein, p17 that is expressed at low levels in HaSV-infected *Helicoverpa armigera* larval midgut tissue and is involved in packaging of viral RNA (Fig. 1). The viral RNAs (vRNAs) of all sequenced genomes of alphatetraviruses (HaSV), *Dendrolimus punctata* tetravirus and, N β V, have a 5' cap and terminates in a tRNA-like structures at its 3' ends that is thought to function in virus replication. The N β V genome encodes the viral REP that overlaps the CP ORF located at their 3' end and the CP is translated from a subgenomic (sg) RNA originating just upstream of the CP coding sequence (Fig. 1).

Permutotetraviridae

There are currently only two permutotetravirus species, namely *Euprosteria elaeasa* virus (EeV) and the type species, *Thosea asigna* virus (TaV). Both viruses have monopartite genomes that are highly conserved (82% and 84% identity, respectively) encoding two overlapping ORFs, with the viral REP at the 5' end and the CP at the 3' end (Fig. 1). In contrast to the alphatetraviruses, the 5' terminus of the TaV/EeV vRNA is predicted to be blocked by a viral protein genome linked, VpG, while the 3' terminus is predicted to form a conserved pseudoknot. The permutotetravirus CP is translated from a sgRNA originating just upstream of the CP ORF.

Table 1 Taxonomic classification of tetraviruses

<i>Virus spécifs</i>		Acronym	Lepidopteran host family	Geographical location	Particle diameter (nm)	GenBank accession no
Family: <i>Alphatetraviridae</i>						
Genus: <i>Omegatetravir</i>	<i>Nudaurelia capensis</i> ω virus ^a	N ω V	<i>Saturniidae</i>	South Africa	41	[S43937.1]
	<i>Helicoverpa armigera</i> stunt virus	HaSV	<i>Noctuidae</i>	Australia	38	[KX423453.1]; [L37299]
	<i>Dendrolimus punctatus</i> Tetravirus	DpTV	<i>Lasiocampidae</i>	China	40	[AY594352]; [AY594353]

^aType strain for the genus.^bSerologically indistinguishable from N β V (Grace and Mercer, 1976).

The activity of 2A-like processing site located near the N-terminus of the CP results in the production of a 17 kDa amino-terminal peptide (p17) and the 65 kDa α protein (Fig. 1). Permutotetraviruses REPs are structurally related to those of birnaviruses and the Drosophila A virus and distantly related to members of the picorna-like virus superfamily. In both viruses, the MET and HEL domains of REP are absent and the REP displays an internally-permuted C-A-B arrangement of the canonical A, B and C motifs found in palm subdomain of the RdRP, upstream of which is a putative nucleotidylation (VPg) signal.

Carmotetraviridae

Providence virus is the sole species of the *Carmotetraviridae* family. The virus has a monopartite genome with the CP ORF, located at the 3' end of the vRNA and translated from a sgRNA originating just upstream of the CP AUG. Two 2A-like processing sites are present at the amino terminus of the ORF that likely result in the translation of two small peptides of 7 and 8 kDa, along with the α protein of 68 kDa that is subsequently cleaved by maturation-dependent autoproteolytic cleavage to form the β and γ subunits of the mature virus particle (Fig. 1). The PrV REP ORF is upstream of the CP CDS and encodes a read-through stop codon that results in the translation of a smaller replication accessory protein (p40). The RdRp domain of the PrV REP is related to replicases of tombus- and umbraviruses, which are (+ve) ssRNA plant viruses in the carmovirus-like supergroup. Unlike any other tetravirus, the PrV genome encodes a third ORF (p130) at its 5' end, upstream of REP. The p130 ORF encodes a 2A-like processing site at its N-terminus would result in the translation of two products of 17 kDa and 113 kDa, respectively. The function of p130 in the PrV lifecycle is unknown.

Viral Replication

Our understanding of tetravirus replication is based on studies of HaSV (*Alphatetraviridae*) and PrV (*Carmotetraviridae*) because these two viruses infect and replicate in tissue culture cell lines. In studies on HaSV-infected *H. armigera* larvae, RNA1 was detected within three days post infection and RNA2 appeared after a further two days. This implies that RNA1 is replicated in the early stages of infection; delayed RNA2 replication results in the later expression of CP and p17 in the virus lifecycle. Immunofluorescence microscopy studies of HaSV-infected *Spodoptera frugiperda* tissue culture cells shows that virus replication occurs in punctate structures in the host cell cytoplasm. The REP is trafficked to detergent-resistant membranes derived from the secretory pathway and membrane targeting is dependent on the presence of two domains – one located at the N-terminus and the other within the C-terminal within the RdRp domain of the protein.

Fig. 1 Genome organization and gene expression of representative tetraviruses of the *Alphatetraviridae*, *Permutotetraviridae* and *Carmotetraviridae* families. Viral genes encoding the replicase, Capsid Protein precursor (CP) and replication accessory protein of PrV (p40) are indicated on the maps as well as gene products produced by co-translational (2A) processing in EeV and PrV as well as maturation-dependent autoproteolytic cleavage of the capsid α protein to produce the β and γ capsid subunits. Translation products labeled with (?) are predicted to be produced but have yet to be identified in virus infected cells. The positions of 2A-like processing sequences (*) and read-through stop codon ($\blacktriangle$) are indicated. The bent arrow shows the start of the sgRNAs of the monopartite viruses (N β V, EeV and PrV) from which the viral CP is translated. GenBank Accession numbers: KX423453.1 (HaSV RNA1), L37299 (HaSV RNA2), AF102884 (N β V), AF461742 (EeV) and AF062037 (PrV).

The PrV REP also localizes to detergent resistant, punctate structures in the cytoplasm of persistently infected *Helicoverpa zea* MG8 tissue culture cells. In *S. frugiperda* cells expressing EGFP-REP fusion proteins, the REP co-localizes with replicating vRNA so these punctate structures are the site of viral replication in PrV-infected cells. As with HaSV, the PrV REP appears to be associated with vesicles originating from the Golgi and secretory vesicles, thus both viruses likely share the same site of replication. The PrV REP is translated into two viral gene products; a truncated accessory replication protein (p40) resulting from the activity of a readthrough stop codon and the full length REP, which encodes the RdRp domain (Fig. 1). p40 also co-localizes with vRNA and is thought to be involved in the establishment of the viral replication complex.

The Tetravirus Capsid

Capsid Structure

X-ray crystallography and cryo-electron microscopy image reconstruction (cryoEM) have been used to examine the different structural states of tetravirus capsids. The crystal structure of authentic *Nudaurelia capensis* omega virus (N ω V) was determined in 1996–2.8 Å resolution. The virion is structurally indistinguishable from the N ω V virus-like particles (VLPs) made by expressing the 70 kDa CP in a baculovirus system. The VLP packages random cellular RNA and can be purified in a metastable procapsid state, allowing for maturation steps to be exquisitely controlled by changes in pH in a time scale that is amenable to biochemical and structural analysis. These characteristics made maturation of this alphatetravirus one of the most accessible systems for the study of eukaryotic icosahedral virus maturation and dynamics.

The N ω V crystal structure showed that the capsid is icosahedral, 420 Å in diameter, and composed of 240 capsid proteins arranged with $T = 4$ quasi-symmetry. Thus, the 60 icosahedral asymmetric units each have four subunits, named A–D, in unique chemical environments (Fig. 2(a)). The 644 amino acid capsid subunit has three domains: an exterior immunoglobulin (Ig)-like fold, a central β -barrel in tangential orientation, and an interior helix bundle (Fig. 2(a)). The helix bundle is created by the N- and C-termini of the polypeptide before and after the β -barrel fold, and the Ig-like domain is an insert between the E and F β -strands of the barrel. The exterior Ig domain is unique in nonenveloped viruses, has the least conserved sequence among tetravirus subunits and is presumed to be involved in cell binding and virus tropism.

Fig. 2 Structure and dynamics of the alphatetravirus, N ω V, capsid. (a) The subunit organization in the N ω V $T=4$ capsid crystal structure. There are four subunits in the asymmetric unit (A in blue, B in red, C in green, and D in yellow). Icosahedral symmetry axes are marked with white symbols, quasi-symmetry axes are marked with black symbols. Quasi-twofold dimer interfaces occur with the bent A–B or flat C–D conformations (right). The well-ordered C-terminal helices in the C–D subunits comprise a molecular switch that stabilizes the flat interface. (b) Ribbon diagram of the C subunit illustrates the three domain tertiary structure present in all 240 subunits (exterior of capsid on top, interior on bottom). Maturation cleavage occurs within the helical domain between residues Asn₅₇₀ and Phe₅₇₁. The molecular switch, present only in the C or D subunits, is highlighted in magenta. (c) Effect of pH on N ω V maturation and activity. Red arrows indicate the maturation pathway. In the wild-type virus, the procapsid converts to uncleaved capsid with the drop of pH, followed by a maturation cleavage, which locks the particle in capsid conformation after $\sim 10\%$ of the subunits are cleaved. While the large conformational change takes milliseconds, cleavage is a slow process taking, minutes to several hours. The surface of the partially matured N ω V reconstructions are colored according to its dynamic properties as determined by standard deviation maps. Note the progressive particle stabilization promoted by cleavage. In the cross section of matured particles, is possible to visualize a dynamic region at the five-fold axis where the lytic γ peptide resides. Infectivity depends on another conformational transition promoted by high pH (black arrow), when the cleaved particle gains lytic activity. No structural model is available for this condition.

Fig. 3 Cryoelectron microscopy reconstructions of the icosahedral tetravirus virions. All four structures are at $\sim 25\text{--}30$ Å resolution and are viewed down their icosahedral twofold axes. The capsids are ~ 400 Å in diameter and have $T = 4$ quasi-icosahedral symmetry. The capsid morphologies of monopartite and bipartite viruses are closely similar (monopartite at top, bipartite at bottom), but differ between the groups. Most notably, within the triangular facets, $N\beta V$ and PrV have a pitted surface where the alphatetraviruses, $N\omega V$ and $HasV$, surfaces are filled in. The permutotetravirus, TaV , also displays the same pitted surface in negative-stain EM photographs as observed for $N\beta V$ and PrV . The recent crystal structure determination of PrV showed this is mainly due to different rotations of the Ig-like domains relative to the β -barrels when compared to the subunits in the $N\omega V$ crystal structure (see Fig. 2). This supports the suggested role of the Ig-like domain in determining the restrictive host cell specificity of these viruses by displaying distinctly different surfaces to cellular receptors.

The interior helix domain is believed to interact with the packaged vRNA genome and have a role in capsid polymorphism and maturation (see below). In mature capsids, all 240 of the $N\omega V$ capsid subunits have undergone autoproteolysis between residues N_{570} and F_{571} after assembly, leaving the cleaved portion of the C-terminus, called the γ peptide, non-covalently associated with the capsid. This peptide has membrane lytic activity and is essential for virus infectivity. The γ peptide also functions as a quasi-equivalent molecular switch (Fig. 2(a) and (b)). In $N\omega V$, a segment of the γ peptide (residues 608–641) is only ordered in the C and D subunits and functions as a wedge between the ABC and DDD morphological units to prevent curvature and create a flat contact. The interface between two ABC units is bent partly due to the lack of ordered γ peptide. The crystal structure of $HasV$ VLPs is very similar to the $N\omega V$ capsid, presenting a root-mean-square deviation of 1.08. Importantly, tetraviruses subunit structure and the mechanism of autoproteolysis displays a strong relationship with the $T = 3$ insect nodaviruses. Indeed, the β -barrel folds and autocatalytic sites can be superimposed with little variation, with the γ peptide in the nodaviruses also involved in quasi-equivalent switches and membrane lytic activity.

The differences between tetravirus capsids are most pronounced in the Ig-like domain. The crystal structure of PrV at 3.8 Å is the only high-resolution structure of a tetravirus with a monopartite genome. The PrV subunit retains the three domains and a superimposable autoproteolysis site (all four subunits show a clear break at the cleavage site), but the Ig-like domain and the first and last ordered residues of the termini in the helical domain have different positions and structure compared to $N\omega V$ and $HasV$. The different Ig domain position was first observed in the cryo-EM reconstruction of $N\beta V$ as a distinctly different surface structure compared to the omega-like particle surfaces (Fig. 3). Interestingly, the use of subunit termini in PrV is more like that seen in the nodaviruses. The quasi-symmetry switch in PrV has swapped elements compared to the omegatetraviruses and represents a new and unique mixture of structural features among the insect viruses.

Capsid Maturation, Auto-Proteolysis and Dynamics

$N\omega V$ and $HasV$ coat proteins expressed in the baculovirus system assemble into a round and porous metastable VLPs that are 480–490 Å in diameter, called procapsids, when purified at neutral pH 7.6. The procapsid coat proteins remain in the uncleaved precursor form until a reduction in pH. When exposed to acidic conditions (pH 5.0), procapsids undergo a large-scale structural rearrangement (maturation) in which the spherical and porous procapsid condenses into the smaller, angular mature capsid. In $N\omega V$ the structural transition triggers the autocatalytic cleavage, where the 70 kDa α protein begins to cleave into the β (62 kDa) and γ (8 kDa) polypeptides, in a reaction that proceeds even at neutral pH (Fig. 2(b)). Small angle X-ray scattering demonstrated that the pH-induced large conformational change occurs in less than 100 ms in $N\omega V$, while the autocatalytic cleavage of all subunits takes several hours to complete. Structure Analysis

Mutagenesis studies have shown the asparagine at the scissile bond (N₅₇₀) in N ω V is required for cleavage. Substituting threonine for asparagine (N₅₇₀T) results in assembly of procapsids that do not cleave but continue to undergo the conformational change reversibly as a function of pH (Fig. 2(b)). Cryo-EM structures at 8 Å resolution of cleaved and N₅₇₀T VLPs demonstrated the role of cleavage in stabilizing the capsid form. There are more extensive inter-subunit contacts in cleaved particles that result in more ordered C-terminal helices, which account for the additional stability of the particle.

Cryo-EM was used to compare particles at intermediate stages of cleavage. Since these intermediates have the same size as a mature capsid, they are superimposable, allowing a detailed analysis of the structural differences in the cleavage site. N ω V maturation has also served as a model for the development of an innovative method for Cryo-EM image reconstruction that captures the dynamic character of viruses displayed in the CryoEM ensemble of particles at the moment of freezing. The result is a quantitative portrait of the structural variance derived from protein dynamics. With this method it was possible to quantify the progressive capsid stabilization during maturation (Fig. 2(b)). Another relevant finding reproduced by both analysis approaches was that the four quasi-equivalent subunit positions of N ω V cleave at different rates and have specialized functions in the particle. γ peptide derived from the pentamer subunits are produced first and are organized in a vertical helical bundle that is projected towards the particle surface. The identical polypeptides in other quasi-equivalent subunits are produced later and act as molecular switches. They make extensive monovalent contacts and are trapped in positions inappropriate for release. Functional data derived from liposome assays provided experimental support for the hypothesis that the pentameric helical bundle is a specialized lytic domain of the capsid structure. The lytic activity of mature capsids against cellular membranes is triggered by alkaline conditions (Fig. 2(b)). This condition is found in the mid-gut of the larvae and seems to be required for infectivity of HaSV virions (see next).

Pathology

Symptoms and Transmission

Tetraviral infection of lepidopteran larvae occurs primarily by ingestion and the symptoms of infection vary widely between the tetraviruses. *Trichoplusia ni* virus (TnV), when it infects *Trichoplusia ni* larvae, causes only a slight retardation in the growth of the larvae. This is in contrast to N β V, which are lethal to infected *N. capensis* larvae and can act rapidly. N β V-infected *Antheraea eucalypti* larvae could appear healthy and be feeding normally but within 12 h, they would be dead. Larvae dying of an N β V infection exhibit certain characteristics: they either hang from the branches by the prolegs or fall to the ground and the contents of their bodies liquefy. All infection studies have shown that the stage at which the tetravirus infection occurs is critical to the outcome. Early instar (L1-L3) *H. armigera* larvae infected with HaSV cease to feed within 24 h, stunt dramatically, liquefy and die within 4 days. Infection of larvae as later instars does not result in any detectable symptoms or lethality, although the larvae do test positive for the presence of HaSV. There have been no reports of infection of pupae or adults by tetraviruses, but there is evidence that vertical transmission may occur.

Host Range

It was a long held belief that tetraviruses replicate only in lepidopteran midgut cells. Tetraviral infection, based on data collected from HaSV infection of *H. armigera* larvae is focused in the midgut of the animal. Regardless of whether HaSV was fed to the larvae or injected into the hemocoel of the animal, vRNA could be detected only in the midgut. Infected cells undergo apoptosis and are sloughed from the midgut of the animal. It is proposed that the virus exploits this host cell response because apoptosis induces cellular acidification, which would induce maturation of the tetravirus particles. The carmotetravirus, PrV, is also targeted to the larval midgut, being first identified as a persistent infection in a *H. zea* midgut (MG8) cell line.

Recent findings, however, indicate that HaSV and PrV can infect other lepidopteran cell types as well. Both PrV and HaSV readily infect and replicate in *S. frugiperda* Sf9 cells, which were derived from *S. frugiperda* wing bud tissue and PrV has also been shown to infect *Spodoptera exigua* 1 cells. An explanation for the apparent tropism of tetraviruses to midgut tissue is provided by the observation that HaSV virus particles require structural rearrangements brought about by exposure to alkaline pH to facilitate binding host cell receptors followed by entry and infection of *S. frugiperda* Sf9 cells. These alkaline pH conditions are provided by only the lepidopteran midgut and hence infection is confined to midgut tissues.

The host range of carmotetraviruses has recently broadened beyond lepidopteran insects. PrV has been shown to infect and replicate in human cervical (HeLa) and breast (MCF7) cancer cell lines. Remarkably, PrV particles purified from *H. zea* MG8 cells are able to productively infect *Vigna unguiculata* (cowpea) plants. vRNA can be detected at sites distant from the site of infection and PrV particles purified from cowpea plants are capable of infecting and establishing replication in mammalian cancer cell lines. These data reveal that PrV is a virus that has crossed Kingdom boundaries retaining the ability to infect and replicate in animal and plant cells. While species of the *Nodaviridae* family have a similar host range, the initiation of replication in yeast, plant and mammalian cells needs to be launched from transfected cDNA or RNA.

Persistent Infections

PrV was the first tetravirus known to replicate in tissue culture. The virus was first isolated from a persistently infected *H. zea* MG8 cell line and subsequently, PrV has been observed to establish persistent infections in other lepidopteran cell lines including

Fig. 4 PrV infected *H. zea* midgut cells express the intestinal stem cell marker Delta. Detection of CP, Delta and p40/REP in persistently infected *H. zea* FB33 (a) and MG8 (b) tissue culture cell lines. Cells were probed with rabbit polyclonal anti-PrV CP and anti-rabbit AF633 secondary antibodies to detect the PrV CP. Mouse anti-Delta and anti-mouse AF546 were used to detect the Delta protein. Viral replicase was stained with biotin-conjugated anti-PrV p40 polyclonal antibodies and streptavidin AF488 to detect the PrV REP. All images represent 1 μ m optical slices taken using a Zeiss LSM780 laser scanning confocal microscope using a X63, 0.75 NA objective. Scale bar represents 10 μ m. (c) Cell-free lysates from PrV-infected *H. zea* FB33 and MG8 cells were separated on an SDS-PAGE gel and western analysis to detect the PrV CP using anti-PrV CP (rabbit) polyclonal and anti-rabbit horse-radish-peroxidase (HRP)-conjugated (goat) secondary antibodies and Delta was detected using anti-Delta (mouse) primary and anti-mouse HRP (goat) secondary antibodies.

an *H. zea* fat body (FB33) and *S. frugiperda* (Sf9) wing bud cell lines. PrV is also able to replicate persistently in human HeLa cells. Lepidopteran larval midgut tissues contain multipotent intestinal stem cells that could be involved in the establishment of persistent PrV infections. Delta, a marker of insect stem cells, is involved in Notch signaling and in the midgut of insects, cellular Delta protein levels are thought to determine the cell fate. High levels of Delta protein activate the Notch pathway, which in turn leads to the down-regulation of Delta in the daughter cells resulting in the cells becoming enterocytes. On the other hand, cells with low levels of Delta are destined to become enteroendocrine cells. Therefore it is the cellular levels of Delta that decides the fate of the cell. PrV infection appears to either target Delta expressing cells or to induce Delta expression in *H. zea* MG8 cells (Fig. 4(b,c)). However, Delta is not expressed in persistently infected *H. zea* FB33 cell line (Fig. 4(a,c)) suggesting that PrV persistence does not involve the infection of insect midgut stem cells.

Concluding Remarks

Since the discovery of N β V, tetraviruses have been defined as small (+ve) ssRNA viruses that share a distinctive $T = 4$ capsid architectures. Their non-structural genes, however, are representative of three diverse virus supergroups, the alpha-like (type IV), the carmo-like (type II) and the picorna-like (type I) supergroups. This implies that modern tetraviruses are the result of converging evolutionary paths that resulted from re-assortment between diverse animal and plant (+ve) ssRNA ancestral viruses. The availability of metatranscriptomic sequence data has significantly extended the extent of the invertebrate virosphere, and there are reports of potentially new tetravirus species. However, these data are based on homology with tetravirus REP sequences. The conserved tetravirus CP is not present on the reconstructed viral genomes and therefore these viruses cannot be considered to be tetraviruses based upon the current definition. The ability of tetravirus capsids to package non-viral RNAs certainly facilitates the evolution of new, re-assorted viruses in the lepidopteran midgut that must be ongoing and undoubtedly, will result in the discovery of new tetravirus species in the future.

Dennis H. Bamford, PhD, is Professor Emeritus of Virology at the Faculty of Biological and Environmental Sciences, University of Helsinki, Finland. He obtained his PhD in 1980 from the Department of Genetics, University of Helsinki. During 1981–1982 he was an EMBO postdoctoral fellow at the Public Health Research Institute of the City of New York, United States, and during 1983–1992 he worked as a Senior Scientist at the Academy of Finland. In 1993 he was appointed Professor of General Microbiology at the University of Helsinki. He was awarded the esteemed Academy Professorship twice, in 2002–2007 and 2012–2016, and he also served twice as the Director of the Finnish Center of Excellence (in Structural Virology, 2000–2005, and in Virus Research, 2006–2011). Prof. Bamford has had continuous external research funding (e.g., from several European Union, Academy of Finland, TEKES and Jusélius Foundation funds, as well as the Human Frontier Science Program). He is an EMBO member and has held several positions of trust in scientific and administrative organizations.

Prof. Bamford has published approx. 400 articles in international peer-reviewed journals in virology, microbiology, biochemistry, and molecular biology (36 of them in high impact journals). About half of the primary articles have been published with international collaborators showing high international integration. He has also been invited to give 56 keynote and plenary presentations in major international meetings. Prof. Bamford has supervised over 35 Master's and

over 40 PhD theses. Seven of his graduate students or post docs have obtained a professorship and a similar number have a principal investigator status. Prof. Bamford has studied virus evolution from a structure-centered perspective, showing that seemingly unrelated viruses, such as bacteriophage PRD1 and human adenovirus have similar virion architecture. When the corona virion architecture was gradually revealed, it was observed that its structural elements were close to those seen in RNA bacteriophage phi6 so that phi6 has been actively used as surrogate for pathogenic viruses - quite a surprise!

Dr. Mark Zuckerman is Head of Virology, Consultant Medical Virologist, and Honorary Senior Lecturer at South London Specialist Virology Centre, King's College Hospital NHS Foundation Trust and King's College London Medical School, Department of Infectious Diseases, School of Immunology and Microbial Sciences in London, United Kingdom. His interests include the clinical interface between developing molecular diagnostic tests relevant to the local population of patients, respiratory virus infections, herpesvirus infections in immunocompromised patients and blood-borne virus transmission incidents in the healthcare setting. He has chaired the UK Clinical Virology Network, Royal College of Pathologists Virology Specialty Advisory Committee and Virology Examiners Panel and is a member of the Specialty Advisory Committee on Transfusion Transmitted Viruses. He is a co-author on four editions of the "Mims' Medical Microbiology" textbook, has written chapters in a number of other textbooks and has over 100 publications in international peer-reviewed journals and is an associate editor for two journals.

SECTION EDITORS

Claude Fauquet received his PhD in biochemistry from University Louis Pasteur in Strasbourg, France in 1974. Dr. Fauquet joined the Institut de Recherche pour le Développement (IRD) and worked there as a plant virologist for 28 years, and served in Ivory Coast, West Africa for 14 years. In 1991, he founded the International Laboratory for Tropical Agricultural Biotechnology (ILTAB) at The Scripps Research Institute, CA, United States. ILTAB was then hosted by the Donald Danforth Plant Science Center, St. Louis, MO, from 1999 to 2012. In 2003, he co-founded the Global Cassava Partnership for the 21st Century (GCP21), which he directed until 2019 and which goal is to improve the cassava crop worldwide.

Dr. Fauquet is an international leader in plant virology including taxonomy, epidemiology, molecular virology, and in gene-silencing as an antiviral strategy. He was Secretary of the International Committee on Taxonomy of Viruses (ICTV) for 18 years and the editor of several ICTV Reports including the VIIIth ICTV Report in 2005.

He has published more than 300 research papers in reviewed journals and books. He is a fellow of the American Association for the Advancement of Science, of the American Phytopathological Society and a member of the St. Louis Academy of Sciences. In 2007, Dr. Fauquet was knighted “Chevalier de l’Ordre des Palmes Académiques” by the French Minister of High Education and Research.

Dr. Michael Feiss is Professor Emeritus in the Department of Microbiology and Immunology of the Carver College of Medicine at the University of Iowa, IA, United States. Dr. Feiss received his PhD in Genetics at the University of Washington followed by a postdoctoral traineeship in the laboratory of Dr. Allan Campbell at Stanford. Dr. Feiss is a microbial geneticist who studies virus assembly with an emphasis on how a DNA virus, bacteriophage lambda, packages viral DNA into the empty prohead shell. The lab investigates how sites in the viral DNA orchestrate the initiation and termination of the DNA packaging process. This work includes comprehensive examination of the DNA recognition sites. A related interest is study of terminase, the viral DNA packaging enzyme, including the functional domains for protein–DNA and protein–protein interactions. A second focus has been the roles of the bacterial host’s IHF and DnaJ proteins in the lytic life cycle of the virus. More recent work has involved a genetic dissection of the role of terminase’s ATPase center that powers translocation of viral DNA into the prohead. This interest in the ATP hydrolysis-driven packaging motor involves a multidisciplinary collaboration examining the kinetics of DNA packaging during individual packaging events. Finally, recent studies have also looked at how the packaging process has diverged among several lambda-like phages, including phages 21, N15, and Gifsy-1.

Elizabeth E. Fry is a senior postdoctoral scientist in structural biology at the University of Oxford, Oxford, United Kingdom, where she received her DPhil. for studies relating to the structure determination of Foot-and-Mouth Disease Virus. Specializing in structural virology, Dr. Fry has studied many virus/viral protein structures but her primary focus is on picornavirus structure and function, in particular receptor interactions and virus uncoating. She is particularly interested in rationally designing virus-like-particles as next generation vaccines to reduce the inherent risks in handling live viruses.

Said A. Ghabrial[†] received his BSc in 1959 from Cairo University, Cairo, Egypt, and his PhD from Louisiana State University, Baton Rouge, LA, United States, in 1965. Dr. Ghabrial did postdoctoral research at the University of California, Davis, CA, United States, before returning to Cairo, where he served as a plant virologist in the Ministry of Agriculture. He returned to the United States in 1970 to do postdoctoral research at Purdue University, West Lafayette, IN. In 1972, he joined the Plant Pathology Department at the University of Kentucky, Lexington, KY, United States, where he rose to the rank of professor in 1986 and worked until 2013.

Dr. Ghabrial has served as an associate and senior editor of *Phytopathology*. He served on the editorial boards of the *Encyclopedia of Virology*, 3rd edition and *Encyclopedia of Plant Pathology*, and edited a thematic issue of *Advances in Virus Research* on "Mycoviruses". He was a member of the American Phytopathological Society (APS) and the American Society for Virology (ASV); in July 2002 he was elected as a Fellow of the American Phytopathological Society. He also acted as Chair of the ICTV Subcommittee on Fungal Viruses in 1987–1993 and 2011–2014.

His long professional career allowed him to make many scientific achievements in phytopathology and virology. Among them are molecular dissection of a legume-infecting RNA virus, bean pod mottle virus (BPMV), development of BPMV-based vectors, discovery of a transmissible debilitation disease of the phytopathogenic ascomycete, *Helminthosporium victoriae* (*Cochliobolus victoriae*), establishment of a viral etiology of the *H. victoriae* disease, and advancement of structural biology of diverse fungal viruses.

Eric Hunter, PhD, is Professor of Pathology and Laboratory Medicine at Emory University, Atlanta, GA, United States. He serves as Co-Director of the Emory Center for AIDS Research and is a Georgia Research Alliance Eminent Scholar.

Dr. Hunter's research focus has been the molecular virology and pathogenesis of retroviruses, including human immunodeficiency virus. He has made significant contributions to the understanding of the role of retroviral glycoprotein structural features during viral entry and providing unique insights into the assembly and replication of this virus family. In recent years the emphasis of his research has been on HIV transmission and pathogenesis, defining the extreme genetic bottleneck and selection of viruses with unique traits during HIV heterosexual transmission. He has described the selection of fitter viruses at the target mucosa, a gender difference in the extent of selection bias, and a role for genital inflammation in reducing selection. His research has defined the impact of HIV adaptation to the cellular immune response on immune recognition and control of HIV after

transmission, as well as on virus replicative fitness in vitro and in vivo. Recent work highlights the roles that virus replicative fitness and sex of the host play in defining disease progression in a newly infected individual. His bibliography includes over 300 peer-reviewed articles, reviews, and book chapters. He has also been the recipient of four NIH merit awards for his work on retrovirus and HIV molecular biology.

Dr. Hunter served as the Editor in Chief of the journal *AIDS Research and Human Retroviruses* for 10 years. He was Chair of the AIDS Vaccine Research Subcommittee which is charged with providing advice and consultation on AIDS vaccine research to the National Institute of Allergy and Infectious Diseases and continues to serve on editorial boards for several academic journals and on external advisory committees for several government, academic, and commercial institutions.

Ilkka Julkunen graduated as an MD/PhD in 1984 from the Department of Virology, University of Helsinki, Helsinki, Finland. He worked as a postdoctoral research fellow at Memorial Sloan-Kettering Cancer Center in New York, United States, in 1986–1989, followed by positions as a senior scientist, group leader and research professor at Finnish Institute for Health and Welfare in 1989–2013. In 2013 he became a Professor of Virology at the University of Turku, Turku, Finland. The research interests of Dr. Julkunen have concentrated on innate and adaptive humoral immunity in viral and microbial infections. He has studied intracellular signaling and RIG-I and TLR-mediated activation of interferon system in human macrophages and dendritic cells and stable cell lines in response to human and avian influenza, Sendai, Zika and coronavirus infections. In addition, he has analyzed the downregulation of innate immunity by viral regulatory proteins from influenza, HCV, flavi-, filo- and coronaviruses. He has expertise in vaccinology, biotechnology and development of methods to analyze antiviral immunity, he has also been actively involved in research training and collaborations with biotechnological industry.

[†]Deceased.

Peter Krell started his career in virology early as a summer high school student working for the Canadian Forestry Service studying the resistance of nuclear polyhedrosis viruses (now called baculoviruses) to environmental exposure with Dr. Fred T. Bird at the Insect Pathology Research Institute in Sault Ste. Marie, ON, Canada. He received his BSc and MSc in biology from Carleton University studying the iridovirus *Tipula Iridescent Virus* with Dr Peter Lee, in Ottawa, the Canadian capital. For his PhD he headed east to Dalhousie University in Halifax, Nova Scotia on the Atlantic coast. In addition to enjoying the salt sea air, fresh cod, lobster and mussels, he studied the molecular biology of polydnaviruses under the guidance of Dr Don Stoltz. Heading south to Texas A&M University in College Station, TX, United States, as a Postdoctoral Fellow he worked with Dr. Max Summer, of baculovirus fame, and Dr. Brad Vinson continuing to study polydnaviruses, but also became steeped in the early days of molecular baculovirology. He then accepted a faculty position in the Department of Microbiology and Immunology at the University of Guelph in Guelph, ON, Canada. There he switched to baculovirus research, which was more tractable, due in part to available cell cultures and focused on viral DNA replication and functional genomics,

particularly on chitinase, cathepsin and ME53. In collaboration with Dr. Eva Nagy he studied molecular biology of different animal viruses, notably Fowl Avian adenoviruses and their development as vaccine vectors, but also on the birnavirus infectious pancreatic necrosis virus, the coronavirus porcine endemic diarrhea virus, fowlpox virus and the paramyxovirus Newcastle disease virus. He has been involved extensively with virus taxonomy, being active in the International Committee on Taxonomy of Viruses (ICTV) as member of the *Polydnaviridae* and *Baculoviridae* study groups, national representative of Canada on the ICTV, member of the Executive Committee for the ICTV and Chair of the ICTV Invertebrate Virus Subcommittee. In terms of governance, Peter Krell was President of the Canadian Society of Microbiology, Secretary and later President of the Society for Invertebrate Pathology, as well as being on the Editorial Boards of the *Canadian Journal of Microbiology* and the *ASM Journal of Virology*. While at the University of Guelph, he rose through the ranks to Professor and is currently University Professor Emeritus.

Mart Krupovic is the Head of the Archaeal Virology Unit in the Department of Microbiology at the Institut Pasteur of Paris, France. He received his MSc in Biochemistry in 2005 from the Vilnius University, Vilnius, Lithuania and PhD in 2010 in general microbiology from the University of Helsinki, Helsinki, Finland. His current research focuses on the diversity, origin, and evolution of viruses, as well as molecular mechanisms of virus–host interactions in archaea. He has published over 170 journal articles and serves as an editor or on the editorial boards of *Biology Direct*, *Research in Microbiology*, *Scientific Reports*, *Virology*, and *Virus Evolution*. He is also a member of the Executive Committee of the International Committee on Taxonomy of Viruses (ICTV) and chairs the Archaeal Viruses Subcommittee of the ICTV.

Maija Lappalainen, MD, PhD, Associate Professor of Clinical Microbiology, is the Head of Clinical Microbiology in the HUS Diagnostic Center, HUSLAB, University of Helsinki and Helsinki University Hospital, Helsinki, Finland. In her thesis during the years 1987–1992 she studied the incidence and diagnostics of congenital toxoplasmosis. After PhD, her research interest has been in diagnostic clinical virology, viral hepatitis, respiratory infections, viral infections in the immunocompromised patients and viral infections during pregnancy.

Hubert G.M. Niesters (1958) studied biology and chemistry in Nijmegen, the Netherlands. After obtaining his PhD in Utrecht (Prof. dr. M. Horzinek and Prof. dr. B. van der Zeijst, 1987) on the molecular epidemiology of infectious bronchitis virus, he worked as a post-doctoral fellow with Prof. dr. Jim Strauss at the California Institute of Technology (Pasadena, United States) on the replication of Alphaviruses. He received a Niels Stensen fellowship (The Netherlands) and an E.S. Gosney fellowship (Caltech) during this period.

After returning to the Netherlands (1989), he became a research associate in medical microbiology at the Diagnostic Medical Center (Delft) but moved back to clinical virology as a senior research associate in 1991 at the Erasmus University Medical Center Rotterdam (Head Prof. dr. Ab Osterhaus). From 1993 to 2007, he was responsible for the molecular diagnostics unit. During this period, he was involved in the discovery and characterization of several new viruses and variants. In 2007, he became full professor and director of the Laboratory of Clinical Virology within the Department of Medical Microbiology at the University Medical Center Groningen and University of Groningen.

He has been actively involved in the implementation and development of new technologies like real-time amplification and automation within clinical virology. He has been focusing on molecular diagnostics and its use and the clinical value in a transplant setting, as well as in monitoring treatment of hepatitis viruses. Recently, his interest focuses on rapid regional epidemiology, automation including MiddleWare solutions for molecular diagnostics, as well as the cost-benefit of rapid point-of-impact molecular testing. Special interest is focused on raising awareness for the detection of enteroviruses (enterovirus D68) and its relationship with acute flaccid myelitis (AFM).

Since 2017, he is the Chair of the executive board of QCMD (Quality Control of Molecular Diagnostics, Glasgow). He is an auditor and team leader for the Dutch Council of Accreditation and Co-Editor in Chief of the *Journal of Clinical Virology*. He is an (co)-author of more than 250 peer-reviewed papers, chapters and reviews including emerging viruses, such as enterovirus D68 and hepatitis E virus (H-index 80).

For his entire work, he received in 2016 the “Ed Nowakowski Senior Memorial Clinical Virology Award” from the Pan American Society for Clinical Virology.

Massimo Palmarini is the Director of the MRC-University of Glasgow Centre for Virus Research and Chair of Virology at the University of Glasgow, Glasgow, United Kingdom. A veterinarian by training, his research programs focus on the biology, evolution and pathogenesis of arboviruses and the mechanisms of virus cross-species transmission. His work is funded by the MRC and the Wellcome Trust. Massimo Palmarini has been elected Fellow of the Academy of Medical Sciences, of the Royal Society of Edinburgh and of the Royal Society of Biology and he was a Wolfson-Royal Society Research Merit Awardee. He is a Wellcome Trust Investigator.

David Prangishvili, PhD, Honorary Professor at the Institut Pasteur, Paris, France, and Professor at Tbilisi State University, Tbilisi, Georgia, is one of the pioneers in studies on the biology of Archaea and their viruses. His scientific career spans ex-USSR (Institute of Molecular Biology, Moscow; 1970–1976), Georgia (Georgian National Academy of Sciences, Tbilisi; 1976–1991), Germany (Max-Planck Institute for Biochemistry, Munich; University of Regensburg; 1991–2004) and France (Institut Pasteur, Paris, 2004–2020). In the research groups headed by him, several dozens of new species and eight new families of archaeal viruses have been discovered and characterized, which display remarkable diversity of unique morphotypes and exceptional genome contents. The results of his research contribute to the knowledge on viral diversity on our planet and change the field of prokaryotic virology, leading to the notion that viruses of

hyperthermophilic Archaea form a particular group in the viral world, distinctive from viruses of Bacteria and Eukarya, and to the recognition of the virosphere of Archaea as one of the distinct features of this Domain of Life. David Prangishvili is a member of the Academia Europaea, the European Academy of Microbiology, and the Georgian National Academy of Sciences.

David I. Stuart is MRC Professor of Structural Biology in the Nuffield Department of Medicine, Oxford University, Oxford, United Kingdom, Life Science Director at Diamond Light Source and Director of Instruct-ERIC (pan-European organisation providing shared access to infrastructure and methods for structural biology). He has diverse interests in structural virology from picornaviruses, double-stranded RNA viruses and enveloped RNA viruses. His drive to develop structural techniques led to the determination of the structure of Bluetongue virus (1995) and then the first membrane containing virus, PRD1. More recently, he has been at the fore-front of bringing Cryo-EM technology to bear on virus structure determination and its future role in visualizing virus function in cellulose. In addition to basic science he has a strong commitment to structural vaccinology and the development of antiviral drugs.

Dr. Nobuhiro Suzuki, PhD, received his MSc (1985) in phytopathology and PhD (1989) in virology from Tohoku University in Sendai, Japan. Dr. Suzuki currently serves as a full Professor of the Institute of Plant Stress and Resources, formerly Institute of Plant Sciences and Bioresources at Okayama University and as an Editor of *Virus Research*, *Frontiers in Virology*, *Journal of General Plant Pathology*, *Virology Journal*, and *Biology*. He has also been Guest Editor to *PLoS Pathogens*, *PNAS*, and *mBio*, and an Editorial Board member of *Virology* and *Journal of Virology*.

Suzuki Laboratory focuses on characterization of diverse viruses infecting phytopathogenic fungi and exploration of their interplays. Recent achievements include the discovery of a neo-virus lifestyle exhibited by a (+)ssRNA virus and an unrelated dsRNA virus in a plant pathogenic fungus and of multilayer antiviral defense in fungi involving Dicer. Prior to coming to Kurashiki, Okayama Prefecture, he was a visiting fellow of the Center for Agricultural Biotechnology at the

University of Maryland Biotechnology Institute (UMBI), College Park, MA, United States, for 4 years (1997–2001) to study molecular biology of hypoviruses in the laboratory of Professor Donald L. Nuss. Before visiting UMBI, he served as an assistant professor and a lecturer of the Biotechnology Institute at the Akita Prefectural College of Agriculture, Japan, for 11 years (1988–1998) where he was engaged in a project on molecular characterization of rice dwarf phytoecovirus, a member of the family *Reoviridae*. He received awards from the Japanese Phytopathological Society of Japan and Japanese Society for Virology for his outstanding achievements in plant and fungal virology.

FOREWORD

I am delighted to write the foreword to this wonderful Fourth Edition of the *Encyclopedia of Virology*. The Third Edition was published in 2008, how the world has changed in the intervening years. The release of the updated fourth edition could not be more timely or more prescient. It is superb and a huge tribute to the authors, Elsevier the publisher, and to the brilliant editors, Dennis Bamford and Mark Zuckerman.

SARS-CoV-2 has dominated the world since it emerged in 2019 and affected every continent and every aspect of life. A reminder, if it were needed, of the impact of infectious diseases, the importance of virology and the vulnerability and interconnectivity of our world.

There is no doubt that with rapidly changing ecology, urbanization, climate change, increased travel, and fragile public health systems, epidemics and pandemics will become more frequent, more complex and harder to prevent and contain. Most of these epidemics will be caused by viruses, those we know about and maybe able to predict and some we do not know of that will emerge from animals, plants or the environment. Our changing climate will change the epidemiology of viruses, their vectors and the infections they cause, hence the critical importance of this totally revised Fourth Edition of the *Encyclopedia of Virology* which brings together research and an understanding of viruses in animals, plants, bacteria and fungi, the environment, and among humans. Never has a holistic, one-health understanding been more important.

That starts with an understanding of the fundamentals of virology, a field of science that has been transformed in the years since the Third Edition. An understanding transformed by embracing traditional fields of molecular and structural biology, genomics, and influenced by immunology, genetics, pharmacology and increasingly by epidemiology and mathematics. Events of 2020 and 2021 also show why it is so important to integrate within traditional virology an understanding of the animal and human health and behavior, of climate change and its impact on the ecology of viruses, plant sciences and vectors. And why we must understand the viruses we think we know well, and those viruses less extensively studied. Research is critical to this, research that pushes the boundaries of what we know, has the humility to seek answers to things we do not understand and shares that knowledge with the widest possible community. That research will be most exciting at the interface between disciplines, most impactful when dynamic, open, inclusive, global, and collaborative.

This is what the Fourth Edition of the *Encyclopedia of Virology*, the largest reference source of research in virology sets out to achieve. It is a wonderful contribution to a critical field of knowledge. It contains new chapters, every chapter revised and updated by a dedicated global community who have come together to provide what is a brilliant and inspiring reference. It is an honor to contribute in a very small way to the timely release of the Fourth Edition of the *Encyclopedia of Virology*.

Jeremy Farrar

PREFACE

The fourth edition of the Encyclopedia of Virology is encyclopedic, but we wanted to move away from an alphabetical list, apart from where it was more logical, to a vision that encompassed a different structure. Articles describing novel trends as well as original discoveries in specific subfields of virology have been distributed into a set of five volumes, namely Fundamentals of Virology, Human and Animal Viruses, Plant Viruses, Bacterial, Archaeal, Fungal, Algal and Invertebrate Viruses, and Diagnosis, Treatment and Prevention of Virus Infections.

We had hoped that the new edition would 'go viral' but it was ironic that the time to publication 12 years after the previous edition had been made a bit longer due to a virus infection. The world encountered a devastating global pandemic, COVID-19, caused by a new type of a coronavirus, SARS-CoV-2. Scientists in many disciplines all over the world started immediate efforts to discover solutions as to how to mitigate and stop the spread of the pandemic. Virology moved from being a highly specialized subject to one in which everyone became a virologist, proving just how significant the different aspects of virology are in terms of understanding the nature of viral infection. Since the previous edition, the growth in the field of general virology has been enormous, including huge advances in basic science, identification of novel viruses, diagnostic methods, treatment and prevention. Taking this into account, the introduction of the articles within the Encyclopedia are very timely and crucial for providing a wealth of knowledge of the latest findings in the field of virology to a vast range of people, whether school students, undergraduates, postgraduates, teachers, scientists, researchers, journalists and others interested in infections and the conflict between the host and the pathogen.

Pandemic viruses have become a serious public concern in the changing world. We can ask ourselves whether we have reached the point in which nature can no longer cope with the consequences of increased population density and human activities that are harmful to the environment. Although several pandemics have threatened mankind before, this COVID-19 pandemic has highlighted the massive adverse economic consequences towards the wellbeing of society and the importance of research in virology.

We aimed to produce a Major Reference Work that differs in approach to others and binds all the virology disciplines together. Chapters have been included on origin, evolution and emergence of viruses, environmental virology and ecology, epidemiology, techniques for studying viruses, viral life cycles, structure, entry, genome and replication, assembly and packaging and taxonomy and viral–host interactions. Information has been included on all known species of viruses infecting bacteria, fungi, plants, vertebrates and invertebrates. Additional topics include antiviral classification and examples of their use in management of infection, diagnostic assays and vaccines, as well as the economic importance of viral diseases of crops and their control.

This edition used viral classification according to the 9th Report of the International Committee on Taxonomy of Viruses published in 2012. Updating it to the 10th Report in 2020 was affected by the pandemic and can be found online at <http://ictv.global/report/>.

We wish to acknowledge the hard work, interest, flexibility and patience, during such difficult times both socially and professionally, of everybody involved in the process of writing this edition of the Encyclopedia of Virology, especially Katarzyna Miklaszewska, Priscilla Braglia, Sam Crowe and colleagues at Elsevier. We sincerely thank all the authors and section editors for their excellent contributions to this edition.

Book Cover Image: Viruses are obligate parasites and all cells have their own viruses increasing the total number of viruses to the estimated astronomical number of 10^{31} that extends the number of stars in the universe. The viral string illustrates how pandemic viruses surround the globe. The original picture was created by Dr. Nina Atanasova (Finnish Meteorological Institute and University of Helsinki) and amended by Matthew Limbert at Elsevier.

*Dennis H. Bamford

HOW TO USE THE ENCYCLOPEDIA

Structure of the Encyclopedia

All articles in the encyclopedia are arranged thematically as a series of entries within subjects/sections, apart from volume 2 where there it was more logical to have articles arranged alphabetically.

There are three features to help you easily find the topic you are interested in: a thematic contents list, a full subject index, and contributors.

1. Thematic contents list: The alphabetical contents list, which appears at the front of each volume, lists the entries in the order that they appear in the encyclopedia.
2. Index: The index appears at the end of volume 5 and includes page numbers for quick reference to the information you are looking for. The index entries differentiate between references to a whole entry, a part of an entry, and a table or figure.
3. Contributors: At the start of each volume there is a list of the authors who contributed to all volumes.

University of Liège, Liège, Belgium

Benoît Moury
Plant Pathology Unit, INRAE – French National Institute for Agriculture, Food and Environment, Montfavet, France

Muhammad Mubin
University of Agriculture, Faisalabad, Pakistan

Nicolas J. Mueller
University Hospital of Zurich, Zurich, Switzerland

Emmanuelle Muller
The French Agricultural Research Center for International Development, Joint Research Units–Biology and Genetics of Plant-Pathogen Interactions, Montpellier, France and Biology and Genetics of Plant-Pathogen Interactions, University of Montpellier, The French Agricultural Research Center for International Development, French National Institute for Agricultural Research, Montpellier SupAgro, Montpellier, France

John S. Munday
Massey University, Palmerston North, New Zealand

Jacob H. Munson-McGee
Montana State University, Bozeman, MT, United States and Bigelow Laboratory for Ocean Sciences, East Boothbay, ME, United States

Hacer Muratoğlu
Department of Molecular Biology and Genetics, Karadeniz Technical University, Trabzon, Turkey

Kenan C. Murphy
University of Massachusetts Medical School, Worcester, MA, United States

Ugrappa Nagalakshmi
University of California, Davis, CA, United States

Keizo Nagasaki
Kochi University, Nankoku, Japan

Nazia Nahid
GC University, Faisalabad, Pakistan and University of Agriculture, Faisalabad, Pakistan

Venugopal Nair
The Pirbright Institute, Pirbright, United Kingdom

Remziye Nalçacıoğlu
Department of Molecular Biology and Genetics, Karadeniz Technical University, Trabzon, Turkey

Shigetou Namba
The University of Tokyo, Tokyo, Japan

Rubab Z. Naqvi
National Institute for Biotechnology and Genetic Engineering, Faisalabad, Pakistan

Rachel Nash
The Pirbright Institute, Surrey, United Kingdom

C.K. Navaratnarajah
Purdue University, West Lafayette, IN, United States

Maria A. Navarrete-Muñoz
Biotechvana, Madrid, Spain; Institute of Health Research-Jiménez Díaz Foundation, Autonomous University of Madrid; and Rey Juan Carlos University Hospital, Móstoles, Spain

Jesús Navas-Castillo
Institute for Mediterranean and Subtropical Horticulture "La Mayora"—Spanish National Research Council—University of Malaga, Algarrobo-Costa, Málaga, Spain

Muhammad S. Nawaz-ul-Rehman
University of Agriculture, Faisalabad, Pakistan

Christopher L. Netherton
The Pirbright Institute, Pirbright, United Kingdom

Thu V.P. Nguyen
Baylor College of Medicine, Houston, TX, United States

Annette Niehl
Julius Kühn Institute – Federal Research Center for Cultivated Plants, Braunschweig, Germany

Hubert G.M. Niesters
Department of Medical Microbiology and Infection Prevention, Division of Clinical Virology, University Medical Center Groningen, Groningen, The Netherlands

Jozef I. Nissimov
University of Waterloo, Waterloo, ON, Canada

Norman Noah
London School of Hygiene and Tropical Medicine, London, United Kingdom

Mauricio L. Nogueira
São José do Rio Preto School of Medicine, São José do Rio Preto, São Paulo, Brazil

Johan Nordgren
Linköping University, Linköping, Sweden

C. Micha Nübling
Paul-Ehrlich-Institute, Langen, Germany

Visa Nurmi
University of Helsinki, Helsinki, Finland

Donald L. Nuss
University of Maryland, Rockville, MD, United States

M. Steven Oberste
Centers for Disease Control and Prevention, Atlanta, GA, United States

Hiroyuki Ogata
Institute for Chemical Research, Kyoto University, Kyoto, Japan

Ane Ogbe
University of Oxford, Oxford, United Kingdom

Hanna M. Oksanen
Molecular and Integrative Biosciences Research Program, Faculty of Biological and Environmental Sciences, University of Helsinki, Helsinki, Finland

Graziele P. Oliveira
Federal University of Minas Gerais, Belo Horizonte, Brazil

Francesco Origi
University of Bern, Bern, Switzerland

Nikolaus Osterrieder
Free University of Berlin, Berlin, Germany

Robert A. Owens
Beltsville Agricultural Research Center, Beltsville, MD 20705, United States

Emine Özsahin
University of Guelph, Guelph, ON, Canada

Sergi Padilla-Parra
University of Oxford, Oxford, United Kingdom; Department of Infectious Diseases, Faculty of Life Sciences and Medicine, King's College London, London, United Kingdom; and Randall Division of Cell and Molecular Biophysics, King's College London, London, United Kingdom

Joshua Pajak
Duke University, Durham, NC, United States

Massimo Palmarini
MRC-University of Glasgow Centre for Virus Research, Glasgow, United Kingdom

Amanda R. Panfil
The Ohio State University, Columbus, OH, United States

Marcus Panning
Institute of Virology, Freiburg University Medical Center, Faculty of Medicine, University of Freiburg, Freiburg, Germany

Vitantonio Pantaleo
National Research Council, Research Unit of Bari, Bari, Italy

Anna Papa
Aristotle University of Thessaloniki, Thessaloniki, Greece

Nikolaos Pappas
Utrecht University, Utrecht, The Netherlands

Hanu R. Pappu
Washington State University, Pullman, WA, United States

Kristin N. Parent
*Michigan State University, East Lansing, MI,
United States*

Colin R. Parrish
Cornell University, Ithaca, NY, United States

A. Lorena Passarelli
Kansas State University, Manhattan, KS, United States

Basavaprabhu L. Patil
*ICAR–Indian Institute of Horticultural Research,
Bengaluru, India*

Jade Pattyn
University of Antwerp, Antwerp, Belgium

T.A. Paul
Cornell University, Ithaca, NY, United States

Lillian Pavlik
*Laboratory for Molecular Virology, Great Lakes Forestry
Centre, Sault Ste Marie, ON, Canada*

Susan L. Payne
Texas A&M University, College Station, TX, United States

Michael N. Pearson
The University of Auckland, Auckland, New Zealand

Mark E. Peeples
*Nationwide Children's Hospital, Columbus, OH,
United States and The Ohio State University College of
Medicine, Columbus, OH, United States*

Ben Peeters
*Wageningen Bioveterinary Research, Lelystad,
The Netherlands*

Joseph S.M. Peiris
The University of Hong Kong, Pok Fu Lam, Hong Kong

Malik Peiris
The University of Hong Kong, Pok Fu Lam, Hong Kong

Judit J. Péntzes
*National Institute of Scientific Research – Armand-
Frappier Health Research Centre, Laval, QC, Canada*

Miryam Pérez-Cañamás
*Institute for Plant Molecular and Cell Biology (Spanish
National Research Council–Polytechnic University of
Valencia), Valencia, Spain*

Marta Pérez-Illana
*National Center for Biotechnology, Spanish National
Research Council, Madrid, Spain*

Jaume Pérez-Sánchez
*Institute of Aquaculture Torre de la Sal, Spanish
National Research Council, Castellon, Spain*

Jean-Marie Peron
*Toulouse University Hospital, Toulouse, France and
Toulouse University Paul Sabatier, Toulouse, France*

Karin E. Peterson
National Institutes of Health, Hamilton, MT, United States

Karel Petrzik
*Biology Center CAS, Institute of Plant Molecular
Biology, České Budějovice, Czech Republic*

Mahtab Peyambari
*Pennsylvania State University, State College, PA,
United States*

Sujal Phadke
J. Craig Venter Institute, La Jolla, CA, United States

Hanh T. Pham
*National Institute of Scientific Research – Armand-
Frappier Health Research Centre, Laval, QC, Canada*

Mauro Pistello
University of Pisa, Pisa, Italy

Daniel Ponndorf
John Innes Centre, Norwich, United Kingdom

Leo L.M. Poon
The University of Hong Kong, Pok Fu Lam, Hong Kong

Welkin H. Pope
University of Pittsburgh, Pittsburgh, PA, United States

Minna M. Poranen
University of Helsinki, Helsinki, Finland

Claudine Porta
*The Pirbright Institute, Pirbright, United Kingdom and
University of Oxford, Oxford, United Kingdom*

Samuel S. Porter
*National Institute of Allergy and Infectious Diseases,
National Institutes of Health, Bethesda, MD,
United States and University of Maryland, College Park,
MD, United States*

Frank A. Post
*King's College Hospital NHS Foundation Trust, London,
United Kingdom*

Nils Poulicard
*Interactions Plantes Microorganismes Environnement,
Institut de Recherche pour le Développement, Centre de
coopération internationale en recherche agronomique
pour le développement, University of Montpellier,
Montpellier, France*

David Prangishvili
*Institut Pasteur, Paris, France and Ivane Javakhishvili
Tbilisi State University, Tbilisi, Georgia*

B. V. Venkataram Prasad
Baylor College of Medicine, Houston, TX, United States

Lalita Priyamvada
Centers for Disease Control and Prevention, Atlanta, GA, United States

Simone Prospero
Swiss Federal Institute for Forest, Snow and Landscape Research WSL, Birmensdorf, Switzerland

Elisabeth Puchhammer-Stöckl
Medical University of Vienna, Vienna, Austria

Jianming Qiu
University of Kansas Medical Center, Kansas City, KS, United States

S.L. Quackenbush
Colorado State University, Fort Collins, CO, United States

Killian J. Quinn
King's College Hospital, London, United Kingdom

Diego F. Quito-Avila
Department of Life Sciences, ESPOL Polytechnic University, Guayaquil, Ecuador

Frank Rabenstein
Julius Kühn Institute, Quedlinburg, Germany

Sheli R. Radoshitzky
United States Army Medical Research Institute of Infectious Diseases, Frederick, MD, United States

Saleem U. Rahman
National Institute for Biotechnology and Genetic Engineering, Faisalabad, Pakistan

Mbolarinosa Rakotomalala
FOFIFA, Antananarivo, Madagascar

Norma Rallon
Institute of Health Research-Jiménez Díaz Foundation, Autonomous University of Madrid and Rey Juan Carlos University Hospital, Móstoles, Spain

Robert P. Rambo
Diamond Light Source, Didcot, United Kingdom

Bertha Cecilia Ramirez
The Institute for Integrative Biology of the Cell, The French Alternative Energies and Atomic Energy Commission, French National Center for Scientific Research, University of Paris-Sud, University of Paris-Saclay, Gif-sur-Yvette, France

María D. Ramos-Barbero
University of Alicante, Alicante, Spain

Chris M. Rands
University of Geneva Medical School and Swiss Institute of Bioinformatics, Geneva, Switzerland

Venigalla B. Rao
The Catholic University of America, Washington, DC, United States

Janne J. Ravantti
University of Helsinki, Helsinki, Finland

Mandy Ravensbergen
Wageningen University and Research, Wageningen, The Netherlands

Georget Y. Reaiche-Miller
The University of Adelaide, Adelaide, SA, Australia

D.V.R. Reddy
International Crops Research Institute for the Semi-Arid Tropics, Hyderabad, India

Vishwanatha R.A.P. Reddy
The Pirbright Institute, Pirbright, United Kingdom

Juan Reguera
Aix-Marseille University, French National Center for Scientific Research, Marseille, France and French National Institute of Health and Medical Research, Marseille, France

William K. Reisen
University of California, Davis, CA, United States

Jingshan Ren
University of Oxford, Oxford, United Kingdom

Renato O. Resende
University of Brasilia, Brasilia, Brazil

Peter A. Revill
The Peter Doherty Institute of Infection and Immunity, Royal Melbourne Hospital, Melbourne, VIC, Australia

Félix A. Rey
Institut Pasteur, Paris, France

Lara Rheinemann
University of Utah, Salt Lake City, UT, United States

Simone G. Ribeiro
Embrapa Genetic Resources and Biotechnology, Brasília, Brazil

Daniel Rigling
Swiss Federal Institute for Forest, Snow and Landscape Research (WSL), Birmensdorf, Switzerland

Cristina Risco
Cell Structure Laboratory, National Center for Biotechnology – Spanish National Research Council (CNB-CSIC), Madrid, Spain

Efraín E. Rivera-Serrano

Lineberger Comprehensive Cancer Center, The University of North Carolina at Chapel Hill, NC, United States and Department of Microbiology and Immunology, The University of North Carolina at Chapel Hill, NC, United States

Cécile Robin

INRAE – French National Research Institute for Agriculture, Food and Environment, UMR BIOGECO, Cestas, France

Rodrigo A.L. Rodrigues

Federal University of Minas Gerais, Belo Horizonte, Brazil

Elina Roine

University of Helsinki, Helsinki, Finland

Maria R. Rojas

University of California, Davis, CA, United States

Marilyn J. Roossinck

Pennsylvania State University, State College, PA, United States

Vera I.D. Ros

Wageningen University and Research, Wageningen, The Netherlands

Cristina Rosa

Pennsylvania State University, University Park, PA, United States

Hanna Rose

Leibniz University Hannover, Hannover, Germany

David A. Rosenbaum

University of Florida, Gainesville, FL, United States

Shannan L. Rossi

The University of Texas Medical Branch, Galveston, TX, United States

Michael G. Rossmann[†]

Purdue University, West Lafayette, IN, United States

L. Roux

University of Geneva Medical School, Geneva, Switzerland

Simon Roux

US Department of Energy Joint Genome Institute, Walnut Creek, CA, United States

J. Rovnak

Colorado State University, Fort Collins, CO, United States

David J. Rowlands

University of Leeds, Leeds, United Kingdom

Polly Roy

Department of Pathogen Infection, Faculty of Infectious and Tropical Diseases, London School of Hygiene and Tropical Medicine, London, United Kingdom and University of Reading, Reading, United Kingdom

Aaron P. Roznowski

The University of Texas at Austin, Austin, TX, United States and University of Arizona, Tucson, AZ, United States

Luisa Rubino

Institute for Sustainable Plant Protection, National Research Council, Bari, Italy

Olli Ruuskanen

Turku University Hospital, Turku, Finland

Eugene V. Ryabov

USDA, Agricultural Research Service, Beltsville, MD, United States

Martin D. Ryan

University of St. Andrews, St. Andrews, United Kingdom

Ki H. Ryu

Seoul Women's University, Seoul, South Korea

Hanns-Joachim Rziha

Eberhard Karls University of Tübingen, Tübingen, Germany

Sead Sabanadzovic

Mississippi State University, Starkville, MS, United States

Roghayeh Safari

Cellular and Molecular Epigenetics (GIGA), Liège, Belgium and Molecular Biology (TERRA), Gembloux, Belgium

Azeez Sait Sahul Hameed

C. Abdul Hakeem College, Melvisharam, India

Nicole Samies

University of Alabama at Birmingham, Birmingham, AL, United States

Carmen San Martín

National Center for Biotechnology, Spanish National Research Council, Madrid, Spain

Ruth-Anne Sandaa

Department of Biological Sciences, University of Bergen, Bergen, Norway

Hélène Sanfaçon

Agriculture and Agri-Food Canada, Summerland, BC, Canada

[†]Deceased.

VOLUME 1

The Virus as a Concept – Fundamentals of Virology

A Brief History of Virology <i>David J Rowlands</i>	3
The Origin of Viruses <i>Patrick Forterre and Morgan Gaïa</i>	14
The Virocell Concept <i>Patrick Forterre</i>	23
Virus Taxonomy <i>Jens H Kuhn</i>	28
The Greater Virus World and Its Evolution <i>Eugene V Koonin and Valerian V Dolja</i>	38
The Virus Species Concept <i>Peter Simmonds</i>	47
Genetic Diversity and Evolution of Viral Populations <i>Rafael Sanjuán and Pilar Domingo-Calap</i>	53
Mechanisms of RNA Virus Evolution <i>Lisa M Bono and Siobain Duffy</i>	62
Mechanisms of DNA Virus Evolution <i>Moriah L Szpara and Koenraad Van Doorslaer</i>	71
Paleovirology <i>Clément Gilbert</i>	79
Evolution Steered by Structure <i>Nicola GA Abrescia</i>	87

Pairwise Sequence Comparison in Virology <i>Tao Zhang, Zheng Gong, Tongkun Guo, Zhuang Xiong, and Yiming Bao</i>	100
Computational Analysis of Recombination in Viral Nucleotide Sequences <i>Miguel Arenas</i>	108
Phylogeny of Viruses <i>Alexander E Gorbalenya and Chris Lauber</i>	116
Virus Bioinformatics <i>Nikolaos Pappas, Simon Roux, Martin Hölzer, Kevin Lamkiewicz, Florian Mock, Manja Marz, and Bas E Dutilh</i>	124
Metagenomics in Virology <i>Simon Roux, Jelle Matthijnsens, and Bas E Dutilh</i>	133
Database and Analytical Resources for Viral Research Community <i>Sujal Phadke, Saichetana Macherla, and Richard H Scheuermann</i>	141
Classification of the Viral World Based on Atomic Level Structures <i>Janne J Ravanntti and Nicola GA Abrescia</i>	153
Isolating, Culturing, and Purifying Viruses With a Focus on Bacterial and Archaeal Viruses <i>Katri Eskelin and Hanna M Oksanen</i>	162
High Throughput Sequencing and Virology <i>Graham L Freimanis and Nick J Knowles</i>	175
Single-Virus Genomics: Studying Uncultured Viruses, One at a Time <i>Manuel Martinez-Garcia, Francisco Martinez-Hernandez, and Joaquín Martínez Martínez</i>	184
Biophysical Characterizations in the Solution State <i>Robert P Rambo and Katsuaki Inoue</i>	191
Virus Crystallography <i>Jonathan M Grimes</i>	199
Advanced Light and Correlative Microscopy in Virology <i>Sergi Padilla-Parra, Charles A Coomer, and Irene Carlon-Andres</i>	208
Atomic Force Microscopy (AFM) Investigation of Viruses <i>Alexander McPherson</i>	218
Cryo-Electron Microscopy (CEM) Structures of Viruses <i>David Chmielewski and Wah Chiu</i>	233
Analysis of Viruses in the Cellular Context by Electron Tomography <i>Peijun Zhang and Luiza Mendonça</i>	242
Mathematical Modeling of Virus Architecture <i>Reidun Twarock</i>	248
Principles of Virus Structure <i>Madhumati Sevvana, Thomas Klose, and Michael G Rossmann[†]</i>	257
Structures of Small Icosahedral Viruses <i>Elizabeth E Fry, Jingshan Ren, and Claudine Porta</i>	278
Structural Principles of the Flavivirus Particle Organization and of Its Conformational Changes <i>Stéphane Duquerroy, Arvind Sharma, and Félix A Rey</i>	290
Reoviruses (Reoviridae) and Their Structural Relatives <i>Liya Hu, Mary K Estes, and B V Venkataram Prasad</i>	303

[†]Deceased.

Structures of Tailed Phages and Herpesviruses (<i>Herpesviridae</i>) <i>Montserrat Fàbrega-Ferrer and Miquel Coll</i>	318
Adenoviruses (<i>Adenoviridae</i>) and Their Structural Relatives <i>Gabriela N Condezo, Natalia Martín-González, Marta Pérez-Illana, Mercedes Hernando-Pérez, José Gallardo, and Carmen San Martín</i>	329
Negative Single-Stranded RNA Viruses (<i>Mononegavirales</i>): A Structural View <i>Juan Reguera</i>	345
Structure of Retrovirus Particles (<i>Retroviridae</i>) <i>David K Stammers and Jingshan Ren</i>	352
Structure of Helical Viruses <i>C Martin Lawrence</i>	362
Giant Viruses and Their Virophage Parasites <i>Rodrigo AL Rodrigues, Ana CdSP Andrade, Grazielle P Oliveira, and Jônatas S Abrahão</i>	372
Viral Replication Cycle <i>AJ Cann</i>	382
Viral Receptors <i>José M Casasnovas and Thilo Stehle</i>	388
Bacterial and Archeal Virus Entry <i>Minna M Poranen and Aušra Domanska</i>	402
Nonenveloped Eukaryotic Virus Entry <i>Ian M Jones and Polly Roy</i>	409
Enveloped Virus Membrane Fusion <i>Aurélien A Albertini and Yves Gaudin</i>	417
Genome Replication of Bacterial and Archaeal Viruses <i>Česlovas Venclovas</i>	429
Viral Transcription <i>David LV Bauer and Ervin Fodor</i>	439
Translation of Viral Proteins <i>Martin D Ryan and Garry A Luke</i>	444
Recombination <i>Jozef J Bujarski</i>	460
Assembly of Viruses: Enveloped Particles <i>CK Navaratnarajah, R Warriar, and RJ Kuhn</i>	468
Assembly of Viruses: Nonenveloped Particles <i>M Luo</i>	475
Virion Assembly: From Small Picornaviruses (<i>Picornaviridae</i>) to Large Herpesviruses (<i>Herpesviridae</i>) <i>Ling Zhu, Nan Wang, and Xiangxi Wang</i>	480
Genome Packaging <i>Richard J Bingham, Reidun Twarock, Carlos P Mata, and Peter G Stockley</i>	488
Virus Factories <i>Isabel Fernández de Castro, Raquel Tenorio, and Cristina Risco</i>	495
Release of Phages From Prokaryotic Cells <i>Jesse Cahill and Ry Young</i>	501
Virus Budding <i>Lara Rheinemann and Wesley I Sundquist</i>	519

Vesicle-Mediated Transcytosis and Export of Viruses <i>Efraín E Rivera-Serrano and Stanley M Lemon</i>	529
Vector Transmission of Animal Viruses <i>Houssam Attoui, Fauziah Mohd Jaafar, Rennos Fragkoudis, and Peter PC Mertens</i>	542
The Human Virome <i>Alexia Bordigoni, Sébastien Halary, and Christelle Desnues</i>	552
Epidemiology of Human and Animal Viral Diseases <i>Michael Edelstein</i>	559
Zoonosis, Emerging and Re-Emerging Viral Diseases <i>Janet M Daly</i>	569
Antiviral Innate Immunity: Introduction <i>Friedemann Weber</i>	577
Humoral and T Cell-Mediated Immunity to Viruses <i>Ane Ogbe and Lucy Dorrell</i>	584
Antigenicity and Antigenic Variation <i>Kuan-Ying A Huang, Xiaorui Chen, Che Ma, Dayna Cheng, Jen-Ren Wang, and Wan-Chun Lai</i>	597
Antigen Presentation <i>Andrew J McMichael</i>	601
Defense Against Viruses and Other Genetic Parasites in Prokaryotes <i>Kira S Makarova, Yuri I Wolf, and Eugene V Koonin</i>	606
Defective-Interfering Viruses <i>L Roux</i>	617
Ecology and Global Impacts of Viruses <i>Joanne B Emerson</i>	621
The Role of Retroviruses in Cellular Evolution <i>Andrea Kirmaier and Welkin E Johnson</i>	627
The Role of Bacteriophages in Bacterial Evolution <i>Chris M Rands and Harald Brüssow</i>	633
Viruses and Their Potential for Bioterrorism <i>Dana L Vanlandingham and Stephen Higgs</i>	644
The Use of Viral Promoters in Expression Vectors <i>Ian M Jones</i>	652
Oncolytic Viruses <i>Laura Burga and Mihnea Bostina</i>	658
Biotechnology Approaches to Modern Vaccine Design <i>George P Lomonosoff and Daniel Ponndorf</i>	662
Viruses: Impact on Science and Society <i>Neeraja Sankaran and Robin A Weiss</i>	671

VOLUME 2

Viruses as Infectious Agents: Human and Animal Viruses

Adenoviruses (<i>Adenoviridae</i>) <i>Balázs Harrach and Mária Benkő</i>	3
---	---

African Horse Sickness Virus (<i>Reoviridae</i>) <i>Piet A van Rijn</i>	17
African Swine Fever Virus (<i>Asfarviridae</i>) <i>Linda K Dixon, Rachel Nash, Philippa C Hawes, and Christopher L Netherton</i>	22
Akabane Virus and Schmallenberg Virus (<i>Peribunyaviridae</i>) <i>Martin Beer and Kerstin Wernike</i>	34
Alphaviruses Causing Encephalitis (<i>Togaviridae</i>) <i>Diane E Griffin</i>	40
Anelloviruses (<i>Anelloviridae</i>) <i>Fabrizio Maggi and Mauro Pistello</i>	48
Animal Lentiviruses (<i>Retroviridae</i>) <i>Esperanza Gomez-Lucia</i>	56
Animal Morbilliviruses (<i>Paramyxoviridae</i>) <i>Carina Conceicao and Dalan Bailey</i>	68
Animal Papillomaviruses (<i>Papillomaviridae</i>) <i>John S Munday</i>	79
Astroviruses (<i>Astroviridae</i>) <i>Virginia Hargest, Amy Davis, and Stacey Schultz-Cherry</i>	92
Avian Hepadnaviruses (<i>Hepadnaviridae</i>) <i>Allison R Jilbert, Georget Y Reaiche-Miller, and Catherine A Scougall</i>	100
Avian Herpesviruses (<i>Herpesviridae</i>) <i>Vishwanatha RAP Reddy and Venugopal Nair</i>	112
Avian Influenza Viruses (<i>Orthomyxoviridae</i>) <i>Nicolas Bravo-Vasquez and Stacey Schultz-Cherry</i>	117
Avian Leukosis and Sarcoma Viruses (<i>Retroviridae</i>) <i>Karen L Beemon</i>	122
Bluetongue Virus (<i>Reoviridae</i>) <i>Raghavendran Kulasegaran-Shylini and Polly Roy</i>	127
Borna Disease Virus and Related Bornaviruses (<i>Bornaviridae</i>) <i>Susan L Payne</i>	137
Bovine Leukemia Virus (<i>Retroviridae</i>) <i>Thomas Joris, Roghaiyeh Safari, Jean-Rock Jacques, and Luc Willems</i>	144
Bovine Viral Diarrhea, Border Disease, and Classical Swine Fever Viruses (<i>Flaviviridae</i>) <i>Paul Becher, Volker Moennig, and Norbert Tautz</i>	153
Capripoxviruses, Parapoxviruses, and Other Poxviruses of Ruminants (<i>Poxviridae</i>) <i>Philippa M Beard</i>	165
Chikungunya Virus (<i>Togaviridae</i>) <i>Thomas E Morrison and Stephanie E Ander</i>	173
Circoviruses (<i>Circoviridae</i>) <i>Giovanni Franzo and Joaquim Segalés</i>	182
Coronaviruses: General Features (<i>Coronaviridae</i>) <i>Paul Britton</i>	193
Coronaviruses: Molecular Biology (<i>Coronaviridae</i>) <i>X Deng and SC Baker</i>	198

Crimean-Congo Hemorrhagic Fever Virus and Nairoviruses of Medical Importance (<i>Nairoviridae</i>) <i>Ali Mirazimi, Felicity Burt, and Anna Papa</i>	208
Dengue Viruses (<i>Flaviviridae</i>) <i>Ashley L. St. John and Duane J. Gubler</i>	218
Ebola Virus (<i>Filoviridae</i>) <i>Andrea Marzi and Logan Banadyga</i>	232
Enteroviruses (<i>Picornaviridae</i>) <i>Carita Savolainen-Kopra, Soile Blomqvist, and Petri Susi</i>	245
Enveloped, Positive-Strand RNA Viruses (<i>Nidovirales</i>) <i>L. Enjuanes, AE Gorbalenya, RJ de Groot, JA Cowley, J Ziebuhr, and EJ Snijder</i>	256
Epstein-Barr Virus (<i>Herpesviridae</i>) <i>Lawrence S. Young</i>	267
Equine Herpesviruses (<i>Herpesviridae</i>) <i>Gisela Soboll-Hussey, Nikolaus Osterrieder, and Walid Azab</i>	278
Equine, Canine, and Swine Influenza (<i>Orthomyxoviridae</i>) <i>Janet M. Daly and Japhette E. Kembou-Ringert</i>	287
Feline Calicivirus (<i>Caliciviridae</i>) <i>Margaret J. Hosie and Michaela J. Conley</i>	294
Feline Leukemia and Sarcoma Viruses (<i>Retroviridae</i>) <i>Brian J. Willett and Margaret J. Hosie</i>	300
Fish and Amphibian Alloherpesviruses (<i>Herpesviridae</i>) <i>Maxime Boutier, Léa Morvan, Natacha Delrez, Francesco Origi, Andor Doszpoly, and Alain Vanderplasschen</i>	306
Fish Retroviruses (<i>Retroviridae</i>) <i>TA Paul, RN Casey, PR Bowser, JW Casey, J Rovnak, and SL Quackenbush</i>	316
Fish Rhabdoviruses (<i>Rhabdoviridae</i>) <i>Gael Kurath and David Stone</i>	324
Foot-and-Mouth Disease Viruses (<i>Picornaviridae</i>) <i>David J. Rowlands</i>	332
Fowlpox Virus and Other Avipoxviruses (<i>Poxviridae</i>) <i>Efstathios S. Giotis and Michael A. Skinner</i>	343
Hantaviruses (<i>Hantaviridae</i>) <i>Tarja Sironen and Antti Vaheri</i>	349
Henipaviruses (<i>Paramyxoviridae</i>) <i>Lin-Fa Wang and Danielle E. Anderson</i>	355
Hepatitis A Virus (<i>Picornaviridae</i>) <i>Andreas Dotzauer</i>	362
Hepatitis B Virus (<i>Hepadnaviridae</i>) <i>Peter Karayiannis</i>	373
Hepatitis C Virus (<i>Flaviviridae</i>) <i>Ralf Bartenschlager and Keisuke Tabata</i>	386
Hepeviruses (<i>Hepeviridae</i>) <i>Xiang-Jin Meng</i>	397
Herpes Simplex Virus 1 and 2 (<i>Herpesviridae</i>) <i>David M. Knipe and Richard Whitley</i>	404

History of Virology: Vertebrate Viruses <i>F Fenner</i>	414
Human Boca- and Protoparvoviruses (<i>Parvoviridae</i>) <i>Maria Söderlund-Venermo and Jianming Qiu</i>	419
Human Coronavirus-229E, -OC43, -NL63, and -HKU1 (<i>Coronaviridae</i>) <i>Ding X Liu, Jia Q Liang, and To S Fung</i>	428
Human Cytomegalovirus (<i>Herpesviridae</i>) <i>Edward S Mocarski</i>	441
Human Immunodeficiency Virus (<i>Retroviridae</i>) <i>Blaide Woodburn, Ann Emery, and Ronald Swanstrom</i>	460
Human Metapneumovirus (<i>Pneumoviridae</i>) <i>Antonella Casola, Matteo P Garofalo, and Xiaoyong Bao</i>	475
Human Norovirus and Sapovirus (<i>Caliciviridae</i>) <i>Sumit Sharma, Marie Hagbom, Lennart Svensson, and Johan Nordgren</i>	483
Human Papillomaviruses (<i>Papillomaviridae</i>) <i>Alison A McBride and Samuel S Porter</i>	493
Human Parainfluenza Viruses (<i>Paramyxoviridae</i>) <i>Elisabeth Adderson</i>	502
Human Pathogenic Arenaviruses (<i>Arenaviridae</i>) <i>Sheli R Radoshitzky and Juan C de la Torre</i>	507
Human Polyomaviruses (<i>Papillomaviridae</i>) <i>Melissa S Maginnis</i>	518
Human T-Cell Leukemia Virus-1 and -2 (<i>Retroviridae</i>) <i>Amanda R Panfil and Patrick L Green</i>	528
Infectious Bursal Disease Virus (<i>Birnaviridae</i>) <i>Daral J Jackwood</i>	540
Infectious Pancreatic Necrosis Virus (<i>Birnaviridae</i>) <i>Øystein Evensen</i>	544
Influenza A Viruses (<i>Orthomyxoviridae</i>) <i>Laura Kakkola, Niina Ikonen, and Ilkka Julkunen</i>	551
Influenza B, C and D Viruses (<i>Orthomyxoviridae</i>) <i>Thorsten Wolff and Michael Veit</i>	561
Jaagsiekte Sheep Retrovirus (<i>Retroviridae</i>) <i>James M Sharp, Marcelo De las Heras, Massimo Palmarini, and Thomas E Spencer</i>	575
Japanese Encephalitis Virus (<i>Flaviviridae</i>) <i>Sang-Im Yun and Young-Min Lee</i>	583
Kaposi's Sarcoma-Associated Herpesvirus (<i>Herpesviridae</i>) <i>Anne K Cordes and Thomas F Schulz</i>	598
Marburg and Ravn Viruses (<i>Filoviridae</i>) <i>Courtney Woolsey, Thomas W Geisbert, and Robert W Cross</i>	608
Measles Virus (<i>Paramyxoviridae</i>) <i>Roberto Cattaneo and Michael McChesney</i>	619
Molluscum Contagiosum Virus (<i>Poxviridae</i>) <i>Joachim J Bugert and Rosina Ehmann</i>	629

Mumps Virus (<i>Paramyxoviridae</i>) <i>Stephen A Winchester and Kevin E Brown</i>	634
Murine Leukemia and Sarcoma Viruses (<i>Retroviridae</i>) <i>George R Young and Kate N Bishop</i>	643
Newcastle Disease Virus (<i>Paramyxoviridae</i>) <i>Ben Peeters and Guus Koch</i>	648
Orthobunyaviruses (<i>Peribunyaviridae</i>) <i>Alyssa B Evans, Clayton W Winkler, and Karin E Peterson</i>	654
Parapoxviruses (<i>Poxviridae</i>) <i>Hanns-Joachim Rziha and Mathias Büttner</i>	666
Parechoviruses (<i>Picornaviridae</i>) <i>Sisko Tauriainen and Glyn Stanway</i>	675
Parvoviruses of Carnivores, and the Emergence of Canine Parvovirus (<i>Parvoviridae</i>) <i>Colin R Parrish, Ian EH Voorhees, and Susan L Hafenstein</i>	683
Polioviruses (<i>Picornaviridae</i>) <i>Philip D Minor</i>	688
Porcine Reproductive and Respiratory Syndrome Virus and Equine Arteritis Virus (<i>Arteriviridae</i>) <i>Jianqiang Zhang, Alan T Loynachan, Gregory W Stevenson, and Jeffrey J Zimmerman</i>	697
Prions of Vertebrates <i>Jonathan DF Wadsworth and John Collinge</i>	707
Pseudorabies Virus (<i>Herpesviridae</i>) <i>Thomas C Mettenleiter and Barbara G Klupp</i>	714
Rabbit Hemorrhagic Disease Virus and European Brown Hare Syndrome Virus (<i>Caliciviridae</i>) <i>Lorenzo Capucci, Patrizia Cavadini, and Antonio Lavazza</i>	724
Rabbit Myxoma Virus and the Fibroma Viruses (<i>Poxviridae</i>) <i>Peter J Kerr</i>	730
Rabies and Other Lyssaviruses (<i>Rhabdoviridae</i>) <i>Ashley C Banyard and Anthony R Fooks</i>	738
Respiratory Syncytial Virus (<i>Pneumoviridae</i>) <i>Tiffany King, Tiffany Jenkins, Supranee Chaiwatpongsakorn, and Mark E Peebles</i>	747
Rhinoviruses (<i>Picornaviridae</i>) <i>Matti Waris and Olli Ruuskanen</i>	757
Rift Valley Fever Virus and Other Phleboviruses (<i>Phenuiviridae</i>) <i>Tetsuro Ikegami</i>	765
Roseoloviruses: Human Herpesviruses 6A, 6B and 7 (<i>Herpesviridae</i>) <i>Katherine N Ward</i>	778
Rotaviruses (<i>Reoviridae</i>) <i>Juana Angel and Manuel A Franco</i>	789
Rubella Virus (<i>Picornaviridae</i>) <i>Annette Mankertz</i>	797
Saint Louis Encephalitis Virus (<i>Flaviviridae</i>) <i>William K Reisen, Lark L Coffey, Daniele M Swetnam, and Aaron C Brault</i>	805
Severe Acute Respiratory Syndrome (SARS) and Middle East Respiratory Syndrome (MERS) (<i>Coronaviridae</i>) <i>Joseph SM Peiris and Leo LM Poon</i>	814

Severe Acute Respiratory Syndrome Coronavirus 2 (SARS-CoV-2) (<i>Coronaviridae</i>) <i>Malik Peiris</i>	825
Simian Immunodeficiency Virus (SIV) and HIV-2 (<i>Retroviridae</i>) <i>Phyllis J Kanki</i>	827
Sindbis Virus (<i>Togaviridae</i>) <i>Satu Kurkela</i>	837
Tick-Borne Encephalitis Virus (<i>Flaviviridae</i>) <i>Teemu Smura, Suvi Kuivanen, and Olli Vapalahti</i>	843
Transmissible Gastroenteritis Virus of Pigs and Porcine Epidemic Diarrhea Virus (<i>Coronaviridae</i>) <i>Qiang Liu and Volker Gerds</i>	850
Vaccinia Virus (<i>Poxviridae</i>) <i>Yan Xiang and Rebecca K Lane</i>	854
Varicella-Zoster Virus (<i>Herpesviridae</i>) <i>Jeffrey I Cohen</i>	860
Variola and Monkeypox Viruses (<i>Poxviridae</i>) <i>Lalita Priyamvada and Panayampalli S Satheshkumar</i>	868
Vesicular Stomatitis Virus and Bovine Ephemeral Fever Virus (<i>Rhabdoviridae</i>) <i>Peter J Walker and Robert B Tesh</i>	875
West Nile Virus (<i>Flaviviridae</i>) <i>Fengwei Bai and Elizabeth Ashley Thompson</i>	884
Yellow Fever Virus (<i>Flaviviridae</i>) <i>Ashley E Strother and Alan DT Barrett</i>	891
Zika Virus (<i>Flaviviridae</i>) <i>Nikos Vasilakis, Shannan L Rossi, Sasha R Azar, Irma E Cisneros, Cassia F Estofolete, and Mauricio L Nogueira</i>	899

VOLUME 3

Viruses as Infectious Agents: Plant Viruses

An Introduction to Plant Viruses <i>Roger Hull</i>	3
Emerging and Re-Emerging Plant Viruses <i>Sabrina Bertin, Francesco Faggioli, Andrea Gentili, Ariana Manglli, Anna Taglienti, Antonio Tiberini, and Laura Tomassoli</i>	8
Emerging Geminiviruses (<i>Geminiviridae</i>) <i>Muhammad S Nawaz-ul-Rehman, Nazia Nahid, and Muhammad Mubin</i>	21
Movement of Viruses in Plants <i>Manfred Heinlein</i>	32
Plant Antiviral Defense: Gene-Silencing Pathways <i>Vitantonio Pantaleo, Chikara Masuta, and Hanako Shimura</i>	43
Plant Resistance to Viruses: Engineered Resistance <i>Marc Fuchs</i>	52
Plant Resistance to Viruses: Natural Resistance Associated With Dominant Genes <i>Mandy Ravensbergen and Richard Kormelink</i>	60

Plant Resistance to Viruses: Natural Resistance Associated With Recessive Genes <i>Masayoshi Hashimoto, Kensaku Maejima, Yasuyuki Yamaji, and Shigetou Namba</i>	69
Plant Viral Diseases: Economic Implications <i>Basavaprabhu L Patil</i>	81
Retrotransposons of Plants <i>M-A Grandbastien</i>	98
Vector Transmission of Plant Viruses <i>Etienne Herrbach and Quentin Chesnais</i>	106
Viral Suppressors of Gene Silencing <i>Hernan Garcia-Ruiz</i>	116
Virus-Induced Gene Silencing (VIGS) <i>Xu Tengzhi, Ugrappa Nagalakshmi, and Savithramma P Dinesh-Kumar</i>	123
Alfalfa Mosaic Virus (<i>Bromoviridae</i>) <i>L Sue Loesch-Fries</i>	132
Alphaflexiviruses (<i>Alphaflexiviridae</i>) <i>Sergey Y Morozov and Alexey A Agranovsky</i>	140
Alphasatellites (<i>Alphasatellitidae</i>) <i>Rob W Briddon and Muhammad S Nawaz-ul-Rehman</i>	149
Amalgaviruses (<i>Amalgaviridae</i>) <i>Ioannis E Tzanetakis, Sead Sabanadzovic, and Rodrigo A Valverde</i>	154
Badnaviruses (<i>Caulimoviridae</i>) <i>Andrew DW Geering</i>	158
Banana Bunchy Top Virus (<i>Nanoviridae</i>) <i>John E Thomas</i>	169
Barley Yellow Dwarf Viruses (<i>Luteoviridae</i>) <i>Leslie L Domier</i>	176
Bean Common Mosaic Virus and Bean Common Mosaic Necrosis Virus (<i>Potyviridae</i>) <i>Ramon Jordan and John Hammond</i>	184
Bean Golden Mosaic Virus and Bean Golden Yellow Mosaic Virus (<i>Geminiviridae</i>) <i>Francisco M Zerbini and Simone G Ribeiro</i>	192
Beet Curly Top Virus (<i>Geminiviridae</i>) <i>Robert L Gilbertson, Tomas A Melgarejo, Maria R Rojas, William M Wintermantel, and John Stanley</i>	200
Beet Necrotic Yellow Vein Virus (<i>Benyviridae</i>) <i>Sebastian Liebe, Annette Niehl, Renate Koenig, and Mark Varrelmann</i>	213
Benyviruses (<i>Benyviridae</i>) <i>Annette Niehl, Sebastian Liebe, Mark Varrelmann, and Renate Koenig</i>	219
Betaflexiviruses (<i>Betaflexiviridae</i>) <i>Nobuyuki Yoshikawa and Hajime Yaegashi</i>	229
Betasatellites and Deltasatellites (<i>Tolecasatellitidae</i>) <i>Muhammad S Nawaz-ul-Rehman, Nazia Nahid, Muhammad Hassan, and Muhammad Mubin</i>	239
Bluner-, Cile-, and Higreviruses (<i>Kitaviridae</i>) <i>Diego F Quito-Avila, Juliana Freitas-Astúa, and Michael J Melzer</i>	247
Brome Mosaic Virus (<i>Bromoviridae</i>) <i>Guijuan He, Zhenlu Zhang, Preethi Sathanantham, Arturo Diaz, and Xiaofeng Wang</i>	252

Bromoviruses (<i>Bromoviridae</i>) <i>Jozef J Bujarski</i>	260
Bymoviruses (<i>Potyviridae</i>) <i>Annette Niehl and Frank Rabenstein</i>	268
Cacao Swollen Shoot Virus (<i>Caulimoviridae</i>) <i>Emmanuelle Muller</i>	274
Carmo-Like Viruses (<i>Tombusviridae</i>) <i>Miryam Pérez-Cañamás and Carmen Hernández</i>	285
Cassava Brown Streak Viruses (<i>Potyviridae</i>) <i>Basavaprabhu L Patil</i>	293
Cassava Mosaic Viruses (<i>Geminiviridae</i>) <i>James Legg and Stephan Winter</i>	301
Caulimoviruses (<i>Caulimoviridae</i>) <i>James E Schoelz and Mustafa Adhab</i>	313
Cheraviruses, Sadwaviruses and Torradoviruses (<i>Secoviridae</i>) <i>Toru Iwanami and René AA van der Vlugt</i>	322
Citrus Tristeza Virus (<i>Closteroviridae</i>) <i>Moshe Bar-Joseph, Scott J Harper, and William O Dawson</i>	327
Closteroviruses (<i>Closteroviridae</i>) <i>Marc Fuchs</i>	336
Comoviruses and Fabaviruses (<i>Secoviridae</i>) <i>George P Lomonossoff</i>	348
Cotton Leaf Curl Disease (<i>Geminiviridae</i>) <i>Nasim Ahmed, Imran Amin, and Shahid Mansoor</i>	355
Cowpea Mosaic Virus (<i>Secoviridae</i>) <i>George P Lomonossoff</i>	364
Cucumber Mosaic Virus (<i>Bromoviridae</i>) <i>Judith Hirsch and Benoît Moury</i>	371
Dianthovirus (<i>Tombusviridae</i>) <i>Kiwamu Hyodo and Masanori Kaido</i>	383
Endornaviruses (<i>Endornaviridae</i>) <i>Toshiyuki Fukuhara</i>	388
Fimoviruses (<i>Fimoviridae</i>) <i>Toufic Elbeaino and Michele Digiaro</i>	396
Furoviruses (<i>Virgaviridae</i>) <i>Annette Niehl and Renate Koenig</i>	405
Geminiviruses (<i>Geminiviridae</i>) <i>Jesús Navas-Castillo and Elvira Fiallo-Olivé</i>	411
Hordeiviruses (<i>Virgaviridae</i>) <i>Zhihao Jiang, Meng Yang, Yongliang Zhang, Andrew O Jackson, and Dawei Li</i>	420
Idaeoviruses (<i>Mayoviridae</i>) <i>Robert R Martin and Karen E Keller</i>	430
Ilarviruses (<i>Bromoviridae</i>) <i>Aaron Simkovich, Susanne E Kohalmi, and Aiming Wang</i>	439

Luteoviruses (<i>Luteoviridae</i>) <i>Leslie L Domier</i>	447
Machlomovirus and Panicoviruses (<i>Tombusviridae</i>) <i>Kay Scheets</i>	456
Maize Streak Virus (<i>Geminiviridae</i>) <i>Darren P Martin and Aderito L Monjane</i>	461
Nanoviruses (<i>Nanoviridae</i>) <i>Bruno Gronenborn and H Josef Vetten</i>	470
Necro-Like Viruses (<i>Tombusviridae</i>) <i>Luisa Rubino and Giovanni P Martelli[†]</i>	481
Nepoviruses (<i>Secoviridae</i>) <i>Hélène Sanfaçon</i>	486
Ophioviruses (<i>Aspiviridae</i>) <i>Anna M Vaira and John Hammond</i>	495
Orthospoviruses (<i>Tospoviridae</i>) <i>Renato O Resende and Hanu R Pappu</i>	507
Ourmiaviruses (<i>Botourmiaviridae</i>) <i>Gian Paolo Accotto and Cristina Rosa</i>	516
Papaya Ringspot Virus (<i>Potyviridae</i>) <i>Cécile Desbiez and Hervé Lecoq</i>	520
Pecluviruses (<i>Virgaviridae</i>) <i>Hema Masarapu, Pothur Sreenivasulu, Philippe Delfosse, Claude Bragard, Anne Legreve, and DVR Reddy</i>	528
Pepino Mosaic Virus (<i>Alphaflexiviridae</i>) <i>Rene AA van der Vlugt and CCMM Stijger</i>	539
Plant Reoviruses (<i>Reoviridae</i>) <i>Yu Huang and Yi Li</i>	545
Plant Resistance to Geminiviruses <i>Basavaprabhu L Patil, Supriya Chakraborty, Henryk Czosnek, Elvira Fiallo-Olivé, Robert L Gilbertson, James Legg, Shahid Mansoor, Jesús Navas-Castillo, Rubab Z Naqvi, Saleem U Rahman, and Francisco M Zerbini</i>	554
Plant Rhabdoviruses (<i>Rhabdoviridae</i>) <i>Ralf G Dietzgen, Michael M Goodin, and Zhenghe Li</i>	567
Plant Satellite Viruses (<i>Albetovirus, Aumaivirus, Papanivirus, Virtovirus</i>) <i>Mart Krupovic</i>	581
Plum Pox Virus (<i>Potyviridae</i>) <i>Miroslav Glasa and Thierry Candresse</i>	586
Poleroviruses (<i>Luteoviridae</i>) <i>Hernan Garcia-Ruiz, Natalie M Holste, and Katherine LaTourrette</i>	594
Pomoviruses (<i>Virgaviridae</i>) <i>Eugene I Savenkov</i>	603
Potato Virus Y (<i>Potyviridae</i>) <i>Laurent Glais and Benoît Moury</i>	612
Potexviruses (<i>Alphaflexiviridae</i>) <i>Ki H Ryu, Eun G Song, and Jin S Hong</i>	623

[†]Deceased.

Potyviruses (<i>Potyviridae</i>) <i>Adrián Valli, Juan A García, and Juan J López-Moya</i>	631
Quinviruses (<i>Betaflexiviridae</i>) <i>Ki H Ryu and Eun G Song</i>	642
Reverse-Transcribing Viruses (<i>Belpaoviridae, Metaviridae, and Pseudoviridae</i>) <i>Carlos Llorens, Beatriz Soriano, Maria A Navarrete-Muñoz, Ahmed Hafez, Vicente Arnau, Jose Miguel Benito, Toni Gabaldon, Norma Rallon, Jaume Pérez-Sánchez, and Mart Krupovic</i>	653
Rice Tungro Disease (<i>Secoviridae, Caulimoviridae</i>) <i>Gaurav Kumar, Fauzia Zarreen, and Indranil Dasgupta</i>	667
Rice Yellow Mottle Virus (<i>Solemoviridae</i>) <i>Eugénie Hébrard, Nils Poulicard, and Mbolarinosy Rakotomalala</i>	675
Satellite Nucleic Acids and Viruses <i>Olufemi J Alabi, Alfredo Diaz-Lara, and Maher Al Rwahnih</i>	681
Secoviruses (<i>Secoviridae</i>) <i>Jeremy R Thompson</i>	692
Sequiviruses and Waikaviruses (<i>Secoviridae</i>) <i>Lucy Rae Stewart</i>	703
Solemoviruses (<i>Solemoviridae</i>) <i>Cecilia Sarmiento, Merike Sõmera, and Erkki Truve[†]</i>	712
Tenuiviruses (<i>Phenuiviridae</i>) <i>Bertha Cecilia Ramirez and Anne-Lise Haenni</i>	719
Tobacco Mosaic Virus (<i>Virgaviridae</i>) <i>Marc HV Van Regenmortel</i>	727
Tobamoviruses (<i>Virgaviridae</i>) <i>Ulrich Melcher, Dennis J Lewandowski, and William O Dawson</i>	734

DIAGNOSIS

Introduction to Virus Diagnosis and Treatment

Maija Lappalainen, HUS Diagnostic Center, HUSLAB, Clinical Microbiology, University of Helsinki and Helsinki University Hospital, Helsinki, Finland

Hubert GM Niesters, Department of Medical Microbiology and Infection Prevention, Division of Clinical Virology, University Medical Center Groningen, Groningen, The Netherlands

© 2021 Elsevier Ltd. All rights reserved.

There are more than 320,000 mammalian viruses, of which a little over 200 are known to infect humans (Anthony *et al.*, 2013; Woolhouse *et al.*, 2012). The number, however, is steadily increasing. During recent years, we have witnessed the emergence of new viral diseases, such as MERS (Memish *et al.*, 2020), infection caused by Zika virus (Rather *et al.*, 2017), and the COVID-19 pandemic caused by SARS-CoV-2 in 2020 (Hu *et al.*, 2020).

Viral diagnostics is increasingly important in clinical medicine. The growing number of new diseases, the expansion of specific antiviral drugs and the need for effective vaccines poses a challenge for the diagnostic tools available. This volume focuses on clinical virology. It leads us through the presentation of traditional, modern and future diagnostic tools and provides views on how to implement these tools in various clinical settings.

Electron microscopy is a highly valued method allowing visualization of virus particles and combined with antibody-based labeling approaches. It is still the method of choice for identifying ultrastructural changes associated with virus-host cell invasion and replication. Molecular methods, in particular the PCR, have replaced viral culture in many laboratories, limiting the use of this traditional method of virus detection or replacing it altogether. We have to realize that most viruses cannot be grown easily or cannot be grown *in vitro* at all. In special circumstances, however, viral culture may still be needed. Traditional serological assays have largely been replaced by enzyme immunoassays and serodiagnostics are at their best in identifying and pinpointing the time of primary infection, in assessing immune status vs. susceptibility, and in pre-transplant donor-recipient matching.

Challenges with conventional diagnostic methods have been stated in several studies. Only 62% of viral respiratory infections among children can be confidently attributed to known pathogens (Arnold *et al.*, 2008) and in another study, it was demonstrated that in 42.7% of cases of viral gastroenteritis, the pathogen could not be identified with conventional methods (Vu *et al.*, 2019). It has been estimated that up to 40% of viral encephalitis infections remain undiagnosed with modern clinical tests (Kennedy *et al.*, 2017). Therefore, new approaches, like microarrays, sensitive multianalyte methods on microfluidic platforms, and high throughput sequencing (HTS) are needed. In addition, we have to also realize that pathogens can follow a hit-and-run procedure before a clinical syndrome is detected or diagnosed. The data provided with new technology could not only augment diagnostics and help to choose the correct therapy, but also facilitates virological research, since more precise, low-cost and accessible solutions are necessary.

The ongoing COVID-19 outbreak emphasizes the importance of biosafety and biosecurity procedures as well as quality assurance and standardization of diagnostic assays to ensure the appropriate performance of the assays used. Many laboratories already have accreditation according to ISO15189:2015, but as more and more hospitals undergo comprehensive on-site surveys conducted by Joint Commission International (JCI) in order to achieve accreditation, this also highlights the accreditation status of the laboratories they use.

Viruses have a quite simple structure with an encapsidated nucleic acid. They borrow molecular equipment from host cells to complete their replication cycle, thus having only a few targets for antiviral agents. In addition to high costs, the existing antiviral treatments still have safety and efficacy challenges. Fortunately, success stories have also been seen with, for instance, treatment of HIV-1 and hepatitis C, encouraging the development of therapies targeting different steps in the viral replication cycle. Updated reviews about management and treatment of clinically relevant viral diseases will be presented.

Vaccine development normally consists of a series of steps that can take many years. However, urgent need, as noted for the development of a SARS-CoV-2 vaccine, may change the development process. Some of the steps in the research and development process are happening in parallel, while still maintaining strict clinical and safety standards. As an example of triumph of vaccine efficacy, will be the permanent cessation of poliovirus.

The number of potentially pathogenic viruses is very large, while the resources for disease research and development (R&D) are limited. To ensure efforts under WHO's R&D Blueprint are focused and productive, a list of diseases and pathogens are prioritized for R&D in public health emergency contexts. The priority 10 viral diseases are discussed.

In the future, with the developing techniques, the clinical virology laboratories are able to produce an enormous amount of detailed data about viruses, pathogenesis and recovery from the infection. The leading challenge is to fully utilize this data in the patient's clinical management and treatment. The prerequisite for this is good communication and collaboration between laboratory personnel, researchers and clinicians. The improved exchange of information and growing information and knowledge, in turn, significantly aids clinicians in battling viral infections.

Glossary

Å Ångström a unit of length used to define very small distances. One ångström is equal to 10^{-10} m (one ten-billionth of a meter or 0.1 nanometers).

Bacteriophage (Phage) a virus which infects only bacteria.

DNA See Nucleic acid.

Cryo From the Ancient Greek *κρύος* (*kríos*, “icy cold, chill, frost”) and used as a prefix cryo- for the study of biological materials at very low temperatures by electron microscopy.

Diffraction Limit The resolution of a microscope is principally limited by the physics of diffraction. An optical system with performance at the instrument's theoretical resolution limit is said to be diffraction-limited. Ernst Karl Abbe, described the diffraction limit of a microscope as $d = \lambda / 2n \sin \alpha$, where d is the resolvable feature size (resolution), λ is the wavelength of the illumination source, n is the index of refraction of the medium the sample is imaged in, and α is the half-angle subtended by the objective lens. The electron wavelength λ is $\sim 100,000$ times shorter than that of visible light and this difference is key to the greater resolving power of the electron microscope.

ELISA (Enzyme-linked immunosorbent assay) or enzyme immunoassay (EIA) is a technique designed for detecting and quantifying substances such as peptides, proteins, antibodies and hormones. In an ELISA, detection is by a highly specific antibody-antigen interaction.

Freeze Etching Is the sublimation of surface ice under vacuum to reveal details of the freeze fractured face that were originally hidden. The fracture face of the sample can be imaged directly in a SEM or as a metal replica of the fracture face in a TEM.

Freeze Fracture Is a technique where a frozen specimen is broken to reveal internal structures.

Leidenfrost Effect A physical phenomenon in which a liquid, close to a surface that is significantly hotter than the liquid's boiling point, produces an insulating vapor layer that prevents the liquid making physical contact with the hot surface. When a warm sample is placed in a liquid cryogen the film of insulating vapor slows down cooling. Due to the small temperature difference between solid and boiling point for nitrogen even when a very small sample is placed in liquid nitrogen a film of vaporized liquid nitrogen forms around the sample and impedes heat transfer. This limits the cooling rate achieved and prevents vitrification.

Lyophilization Also referred to as freeze-drying, is a technique which utilizes low pressure and low temperature to dry a material by the sublimation of water. Sublimation converts water directly from a solid to a gas without the effect of a change in surface tension (the tendency of fluid

surfaces to shrink into the minimum surface area possible) which increases as liquid water evaporates causing changes to virus morphology.

Negative Stain Contrasting a thin specimen with an optically opaque electron dense fluid. Once dry, the background is stained, leaving the actual specimen untouched, and thus visible in the transmission electron microscope.

Nucleic acid The genetic information of a virus is carried on nucleic acid. Viruses may be divided into those of ribonucleic (RNA) or deoxyribonucleic (DNA) forms.

RNA See Nucleic acid.

SEM Scanning Electron Microscope, a microscopy technique in which a focused beam of electrons is scanned across a surface in a raster scan pattern, and the position of the beam is combined with the intensity of the detected signal to produce an image.

Single Particle Analysis An image processing technique which is applied to TEM images. The approach digitally combines many images of similar small particles (e.g., a virus) to create an image with stronger and more easily interpretable features. Commonly many individual virus particles will be captured in a single photomicrograph and in many photomicrographs thousands of individual randomly orientated viruses exist. Each individually reveal the different unique faces of the virus. Each individual virus may be “boxed out” or digitally cut out and then processed to build up a three-dimensional reconstruction of the particle. Using cryo-electron microscopy it has become possible to generate reconstructions with near-atomic resolution.

TEM Transmission Electron Microscope, a microscopy technique in which a beam of electrons is transmitted through a specimen to form an image.

Tomography A technique for obtaining detailed 3D structures of sub-cellular macro-molecular objects. Electron tomography is an extension of traditional TEM where single 2D images are collected. Instead, the sample is tilted in the TEM at incremental degrees of rotation around the center of the target sample. At each tilt angle the TEM electron beam is passed through the sample and a 2D image collected. Each image is collected and digitally processed using a weighted back projection into a 3D volume of the sample.

Vitrification The transformation of a water by rapid cooling into a non-crystalline amorphous solid, “glass” thus avoiding the crystalline ice states of water and change in volume associated with freezing.

μl A unit of volume used to define a very small volume. 1 μl is equal to one millionth of a litre.

Introduction to Virus Diagnosis by Electron Microscopy

Organisms, causative of disease, commonly occupy a length scale below that visible by the naked eye. Light microscopes readily aid the observation of amoeba and bacteria but are unable to directly observe viruses, which are also a major cause of disease. A simple change to host phenotype may imply the presence of a pathogen further analysis, using specialist techniques and equipment is needed to confirm and identify a virus infection.

The electron microscope (EM) developed by Ernst Ruska and Max Knoll in 1931, to exploit the shorter wavelength of electrons, created an instrument with the potential to overcome the diffraction limits of the light microscope (restricted by the longer wavelengths of visible light). Eight years after the initial EM development, Ruska with Kausche and Pfankuch were able to visualize a virus for the first time. This first view of a tobacco mosaic virus (TMV) heralded the start of modern virology. The initial proof of concept was rapidly followed by images of bacteriophage. The first EM studies on pathogenic viruses were published shortly after, in 1938 by von Borries *et al.*, detailing the size and fine structure of smallpox, vaccinia virus and Ectromelia mouse pox. Soon after, the EM became the *de facto* tool of choice for the virologist. Providing a simple and almost direct way to observe nanometer (nm) scale biological structures. Today, the latest cryo transmission EMs (cryoEM) reveal near atomic level structural information of the virus and its assembly.

Initially, positive staining by the application of phosphotungstic acid and osmium tetroxide to bacteriophage and proteins was tried, however, disruption to structures was observed due to the low pH of the staining solutions. Early studies of fine virus ultrastructure and morphology used the shadow casting techniques devised by Williams and Wyckoff in 1945, whereby a fine metal (e.g., palladium or platinum) was evaporated under vacuum and applied to a dried preparation of virus from a fixed low angle. Shadowed with $\sim 8 \text{ \AA}$ thickness of metal, at an angle of about 12° from the horizontal plane of the mount, the low angle and unidirectional coating created a shadow of the virus as the metal collected on the side of the virus facing the metal evaporation source. When viewed in the transmission electron microscope (TEM) the enhanced contrast between metal shadowed and shaded areas revealed the morphology and fine ultrastructural details of the virus. Although shadow-cast specimens provided useful details from both air-dried and freeze-dried material, the protocol itself is challenging and requires specialist vacuum metal evaporation technology and high quality “near pure” samples.

The method of choice for direct virus detection is negative staining (NS) (Fig. 1). Established by Brenner and Horne as a fast, robust and universal EM technique NS has been used by virologists for over 60 years. The EM NS preparation technique is effective for fresh, aged, partly degenerated, or dried specimens (e.g., vesicle fluid, fecal samples) and can be applied readily to biological tissues; homogenized or mortar ground organs, biopsy (including wart and molluscum contagiosum skin lesions), autopsy specimens and cell cultures (both supernatant and lysed cell pellets). The versatility of NS also allows samples collected from soil and aquatic sources, e.g., from streams, urban irrigation systems, sewage outlets, standing water, lakes etc to be studied and can be used to detect agricultural or human sewage contamination of a eutrophicated water body.

The potential of EM in the laboratory diagnosis of infectious diseases was first demonstrated in the control of smallpox outbreaks and developed into a routine procedure for the detection and diagnosis of common viral diseases by skilled operators. These virus diagnostic EM (DEM) laboratories became ubiquitous in hospitals and public health laboratories globally, providing a routine service for circulating gastrointestinal and respiratory infections. Routinely applied to human pathogens, e.g., viruses of medical importance, with around 21 viral families and genera being deemed medically significant (Table 1), DEM also found wide acceptance in veterinary virology. Due to the potentially serious consequences of viral outbreaks, rigorous, and universally recognized training of personnel dealing with virus identification was required. Today training in Diagnostic Electron Microscopy (DEM) of human and veterinary infectious diseases can be obtained via an annual External Quality Assurance (EQA) scheme prepared and distributed by the Robert Koch Institute (RKI), Berlin.

Diagnostic Transmission Electron Microscopy

The transmission electron microscopy (TEM) is a powerful initial step in virus diagnosis for several reasons. The TEM provides an unbiased direct and rapid overview of the sample. The viral burden (amount), size and shape (critical for initial identification) of virus or viruses present is immediately apparent. The observed morphology, even for unexpected or emerging pathogens normally allows preliminary classification to family level based on particle morphology (Table 1). This “catch all” diagnostic facility is due to TEM sample preparation protocols targeting proteins, the viral capsid or ribonucleoprotein (RNP) complexes rather than the virus RNA or DNA genomes and makes TEM uniquely unbiased as a detection method. Initial identification of a virus requires only very small volumes ($\sim 1 \mu\text{l}$) of samples carrying high virus ($> 10^6$ particles ml^{-1}) loads and can then direct the virologist to further methods (e.g., bioassays, serological, or molecular biology approaches) to identify virus genus and species.

As a technique where identification is by morphology, DEM developed rapidly. During the early 1950s until the mid-1960s many new viruses were discovered and names were commonly assigned on Latinized abbreviations attributed to their morphology or niche and -viridae for virus families and -virus for viral genera (Table 1). Viral morphology and niche provided the basis for grouping viruses into families, be they a virus family able to replicate only in vertebrates, only in invertebrates, only in plants, only in bacteria or less commonly viruses able to replicate in more than one of these hosts. Viruses were then often further grouped or classified on the basis of size and shape, i.e., helical morphology is seen in nucleocapsids of many filamentous and pleomorphic viruses; helical nucleocapsids consist of a helical array of capsid proteins wrapped around a helical filament of nucleic acid.

Fig. 1 Virus particles as revealed by different electron microscopy methods. (A) bacteriophage collected using a transmitted electron detector in a field emission scanning electron microscope (FEGSEM). B-C Influenza virus particles by different electron microscopy techniques (B) prepared by high pressure freezing, freeze fracture and direct imaging in the FEGSEM, (C) prepared by plunge freezing into liquid ethane and imaging at 200 kV by low dose cryo transmission electron microscopy, (D) conventional negative staining of air dried particles with 2% sodium silicotungstate (SST). (E-J) virus particles by negative staining, imaged at 120 kV on a TEM E, (H) parapoxvirus, (F) adenovirus, (G) reoviruses virus particles with monomorph morphology (I) paramyxovirus (J) orthopoxvirus.

Icosahedral morphology is characteristic of the nucleocapsids of many “spherical or cubic” viruses. Some viruses (e.g., herpesvirus) also have an outer envelope which can be readily observed in the EM and can help in identifying the virus.

Despite the role of EM as the first line diagnostic tool for gastrointestinal and influenza infections being superseded by genetic screening approaches (e.g., PCR). EM remains an important diagnostic tool in several clinical settings. Indeed, guidance issued by the UK's Royal College of Pathologists cites the Association of Clinical Pathologists Best Practice No. 160, which states that ‘Many respondents [to a review of laboratory practice in renal pathology] expressed the opinion that to carry out evaluation of renal biopsy specimens without at least having the availability of electron microscopy is negligent’. Other specialized areas include the diagnosis of primary ciliary dyskinesia; certain skin/connective tissue disorders, e.g., inherited bullous lesions and Ehlers–Danlos syndrome; and specialized areas of ophthalmic pathology. The versatility of DEM and the power to directly observe the morphology of virus particles, particularly for unknown or emerging diseases and complex co-infections remains its unique value. This is a specialist niche role and with the reduction in the number of DEM facilities globally one whose essential skilled operator base is increasingly difficult to maintain. Specialist DEM units are now largely maintained at a national level in specialist disease surveillance and control centers and continue to play a critical role as demonstrated by their contribution to the investigations into recent unexplained diseases, potential bioterrorism incidents and zoonoses. The identification of the Severe Acute Respiratory Syndrome (SARS) agent, the unexpected diagnosis of monkeypox virus infections in the USA, Buffalopox infections of humans, arboviruses and viral hemorrhagic fevers in India and Hendra paramyxovirus infections in Australia were by these specialist centers (e.g., the Center for Disease Control and Prevention, Georgia, USA and the National Institute of Virology, Pune, India). Based on its ability to recognize contaminations, rapid application of TEM has an important role for quality control of reference material or of virus preparations used for antibody production or directly for vaccination.

Table 1 Viruses families known to cause disease in humans, the origin of their name, nucleic acid relationship, symmetry of the capsomere as described by classical negative stain diagnostic electron microscopy and commonly observed disease

<i>Virus family</i>	<i>Nucleic acid</i>	<i>Symmetry</i>	<i>Explanation of the origin of family name</i>	<i>Symptoms and associated diseases attributed to the virus family</i>
Picornaviridae	RNA	Icosahedral	pico (small) and RNA	e.g., Coxsackieviruses associated with neurological disease, hand foot and mouth disease and respiratory tract illness in man
Reoviridae	RNA	Icosahedral	respiratory, enteric, and orphan viruses because the agents were found in both respiratory and enteric specimens	Widespread in domestic animals and man, first isolated from respiratory and stool samples
Papovaviridae	DNA	Icosahedral	papilloma, polyoma, and vacuolating agent, now split into Papillomaviridae and Polyomaviridae families	e.g., Human Papilloma Virus (HPV) causing cervical cancers and genital warts
Retrovirus	RNA	Complex	reverse transcriptase	e.g., causing Acquired Immune Deficient Syndrome (AIDS) following infection with the Human Immunodeficiency Virus (HIV)
Hepadnaviridae	DNA	Icosahedral	replication of the virus in hepatocytes and their DNA genomes, as seen in hepatitis B virus.	Including the Hepatitis B virus
Adenoviridae	DNA	Icosahedral	adeno, "gland"; refers to the adenoid tissue from which the viruses were first isolated	Infections are commonly associated with diarrhea in children and adults
Astroviridae	RNA	Icosahedral	astron "star"	small viruses associated with childhood diarrhea
Arenaviridae	RNA	Complex	arena "sand" describes the sandy appearance of the virion.	The causative agent of Lassa fever in man
Bunyaviridae	RNA	Helical	Bunyamwera, the place in Africa where the type strain was isolated	Highly pathogenic in man causing Crimean-Congo hemorrhagic fever, Rift Valley Fever and Nephropathia epidemica
Ebolavirus	RNA	Helical	Ebola River, close to the two simultaneous 1976 outbreaks: one in Nzara (a town in South Sudan) and the other in Yambuku village (Democratic Republic of the Congo) where the virus was first identified.	Morphologically similar to Marburg virus causing hemorrhagic fever in man with high levels of mortality
Calicivirus	RNA	Icosahedral	calix, "cup" or "goblet" from the cup-shaped depressions on the viral surfaces	Commonly infecting cats causing respiratory tract infections in adult cats and fatal pneumonia in kittens, pigs and sealions, also infections in man
Coronaviridae	RNA	Helical	corona, "crown" describes the appearance of the peplomers protruding from the viral surface	often reported as causing "common cold" symptoms in man, human respiratory infections and "gassing disease" in chickens
Filoviridae	RNA	Helical	from the Latin filum, "thread" or "filament" describes the morphology	including the Marburg virus which is highly infectious and pathogenic in man
Herpesviridae	DNA	Icosahedral	herpes, "creeping" describes the nature of the lesions	Including the Epstein Barr virus responsible for Glandular fever (mononucleosis) and cold sores in man
Orthomyxoviridae	RNA	Helical	ortho, "true," plus myxo "mucus," a substance for which the viruses have an affinity.	the viruses responsible for Influenza
Orthopoxviruses	RNA	Complex	combining ortho with pox (pustule) descriptive of the infection	the vaccinia, cowpox, and variola (smallpox) viruses
Paramyxoviridae	RNA	Helical	para, "closely resembling" myxo	including the viruses causing measles, mumps, respiratory syncytial infections and Newcastle disease
Parvoviridae	DNA	Icosahedral	parvus means, "small"	one of smallest DNA viruses and including human parvovirus B19 which was initially discovered in human sera being screens for hepatitis B antigen. A canine variant causes bloody diarrhea in puppies and can lead to death
Poxviridae	DNA	Complex	pock means, "pustule"	Including the pseudopoxvirus which causes udder infections in cows and is commonly named cow pox
Rhabdoviridae	RNA	Helical	rhabdo, "rod" describes the shape of the viruses	causing Rabies, an infection almost always fatal in man
Togaviridae	RNA	Icosahedral	toga, "cloak" refers to the tight viral envelope.	Including the virus responsible for Rubella "German Measles"

To partially address the combined challenges of fewer specialist viral DEM units and the essential requirement for experienced virus DEM specialists, Laue and Möller at the RKI have generated a publicly available database of EM images. Expansion of such archives will facilitate recognition of newly emerging as well as unexpected viruses. For instance, an increase in the local prevalence

of plant viruses can serve as indicators of environmental stress and predict underlying contamination of irrigation water with pathogenic human viruses. Thus, TEM remains an integral part of the surveillance role of national reference laboratories, where prompt, reliable and comparable results are essential for efficient diagnostics during unexpected regional virus outbreaks or epidemics (e.g., rare zoonoses, such as Buffalopox). Despite this longstanding and continued value and capacity to inform, DEM as a tool in the clinical setting has been largely stagnant with little change in the technical procedures or their application for decades. In marked contrast, TEM and particularly cryoEM in the research setting has experienced an explosion in capacity and capability, heralding the “resolution revolution”.

Biological EM Challenges and Sample Preparation

Biological EM is not without its challenges. The electron beam is generated under vacuum at pressures and temperatures that are nominally incompatible with liquid water, yet water is the most abundant cellular constituent. Biological tissues (carbon-based life forms) have poor contrast in the electron microscope because they are composed mainly of light elements. In fact, carbon is so “transparent” in the electron microscope that it is often employed as a film to support biological samples. To overcome these challenges, hydrated “live” tissue is converted to an EM stable state; conventional protocols employ a series of steps, including chemical fixation, alcohol dehydration and resin infiltration. Heavy metal salts are added for positive staining of fixed and embedded specimens or as negative stains of whole structures that have been deposited on a support film. More recently, cryo-fixation has been adopted and allows the “solidification of a biological specimen by cooling with minimal displacement of its components”. By using low temperature as a physical fixation strategy, the morphology and dimensions of the living material are retained, and soluble cellular components are not displaced, which means that processing artefacts commonly encountered in more conventional room-temperature EM techniques are either reduced or removed. CryoEM often allows direct observation of specimens that have not been stained or chemically fixed. However, due to the requirement for the cryo fixed sample to be maintained at cryogenic temperatures and the challenge of avoiding warming and/ or contamination during transfer into the TEM the approach is not regarded as suitable for DEM. Instead, cryoEM is reserved for high resolution research studies.

Small particles like bacteria, viruses and proteins readily lend themselves to a simple protocol able to preserve their ultra-structure and introduce sufficient contrast to make their observation easy. Referred to as negative staining (NS) it is an easy, rapid, qualitative method for examining the structure of isolated organelles, individual macromolecules and viruses at the EM level (Fig. 2). This is the opposite of the stain binding to the sample and excess being removed, in which case a particle would appear dark against bright background (positive staining). Despite providing stunningly beautiful images of viruses, NS does not allow the highest resolution examination of samples.

Negative staining involves the deposition of heavy atom stains, e.g., uranyl acetate, around a small particle to make it visible in the electron beam. Structural artefacts such as flattening of spherical or cylindrical structures are common. Nevertheless, negative staining is a very useful technique because of its ease and speed (taking only a few minutes for a skilled operator), and also because it requires no

Fig. 2 Representation of a negatively stained virus particle on a TEM grid. Negative staining requires very little specialized equipment and virus suspensions can be mounted directly on TEM support grids (e.g., carbon formvar) and examined after air-drying. However, due to their small size and the low atomic numbers of the elements forming the virus particle they provide little electron scattering on interaction with the electron beam (blue dotted lines). This means that they have very low contrast and do not stand out from the background. To visualize the virus, heavy metal (high atomic number, high scattering) stain such as uranyl acetate or phosphotungstic acid is used. The virus particles (smiley face) are surrounded by the stain, which scatters electrons strongly creating negative contrast, whereby the particle appears bright against the stain. As the stain has a small grain size, as it covers the virus particle it is also trapped in surface features. Differences in *z* “thickness” of stain which the electron beam passes through en route to the detector is responsible for variations in the level of signal detected and thus contrast, to reveal gross morphological features and details of subunits forming the protein structures.

Table 2 Common negative stains used for diagnostic electron microscopy. Other less common stains include; aluminum formate, uranyl oxalate, and uranyl sulfate and gold thioglucose

<i>Common negative stains:</i>	<i>Normal range for use (pH)</i>	<i>Normal concentration (w/v)</i>
Phosphotungstic acid (PTA)	5–8	1%–3% aqueous solution
Uranyl acetate (UA)	4.2–4.5	1%–3% aqueous solution
Uranyl formate	4–4.5	0.5%–1% aqueous solution
Sodium silicotungstate (SST)	5–7	1%–5% aqueous solution
Ammonium molybdate	6–7	1%–2% aqueous solution
Methylamine tungstate	5–8	2% aqueous solution

specialized equipment other than that found in a regular EM laboratory. The NS should not react with the specimen in a 'positive staining' manner (i.e., it should not bind to the specimen). However, uranyl based stains will bind to proteins and sialic acid carboxyl groups and to lipid and nucleic acid phosphate groups. One effect of this is to induce aggregation of the material.

General Protocol for the Study of Viruses by Negative Staining

The method of surrounding or embedding specimens in opaque dyes is commonly used in light microscopy and dates from about 1884 (e.g., microbiologists use India ink to stain micro-organisms heat fixed to a slide. The background is stained with the ink while the organisms remain clear, creating a negative stain of the organism). A common clinical application of this procedure is to confirm the morphology of the encapsulated yeast *Cryptococcus* spp. which cause cryptococcal meningitis.

The equivalent preparative technique applied to electron microscopy was derived from experiments on a bacteriophage by high resolution EM in the Cavendish Laboratory, Cambridge, during 1954. When mixed with 1% potassium phosphotungstate and air-dried, gross morphological features of a human adenovirus and details of subunits forming the protein structures were revealed. The approach was first described by Brenner & Horne in 1959 and confirmed the earlier observation of Hall in 1955 working at the Massachusetts Institute of Technology that "bushy stunt virus stained with 5% phosphotungstic acid at pH 4.6 and insufficiently washed is the opposite to what I usually sought by the use of electron stains the viability of particles of low scattering power can be enhanced as well, if not better, by surrounding them with dense material rather than impregnating them with dense material" (*sic*).

Negative staining is as diverse in how it is performed as it is ubiquitous as a rapid technique able to reveal the structure of small biological particles (e.g., viruses and proteins) in the EM. Many heavy metal contrasting stains are available (Table 2). Each has a "fine grain structure" suitable to reveal the fine structure of the virus particle without obscuring virus morphology, is electron dense to create strong contrast between the unstained specimen (the virus) and the surrounding (negative) stain and in almost all cases has the capacity to stabilize or otherwise fix the sample to preserve its structure in the EM.

Fixed or unfixed samples may be used. With unfixed specimens there is the potential problem of changes occurring due to osmotic shock (or to changes in ionic composition) since most negative stains are made up in distilled water. Also, there may be risk of operator infection when examining unfixed bacterial or viral samples.

Samples should be concentrated and purified to allow the operator the best chance of identifying and imaging relevant particles. Cell debris can be removed by centrifugation before loading samples onto grids. Due to the small volumes used in the preparation methods detailed below, the number of biological particles in the sample must exceed 10^6 particles/ml.

There are a number of methods for preparing samples for examination by NS; the method used depends on either the sample to be stained or the method of choice in the laboratory. Below are outlined some of the simpler methods.

Method A Negative Staining Single-droplet method.

- (1) Glow discharge carbon-formvar coated grids just before use to increase their hydrophilicity. This is essential to allow even wetting of the grid with the sample and stain and ensures even NS of the sample.
- (2) Place 1–3 μ l of the sample on the grid (sufficient to cover the grid surface).
- (3) After ~ 10 s slowly pipette 20 μ l of stain on to sample, while gently absorbing the stain from the opposite side using a wedge of filter paper. The staining procedure should take ~ 30 –60 s.
- (4) After absorbing as much stain as possible allow the grid to dry and examine the grid as soon as possible, preferably the same day in the TEM. Some methods include a wash in distilled water after drying which can be helpful if the buffer becomes crystalline when dried or when the sample is too thick on the grid.

Method B.

Sequential two-droplet method.

- (1) A suspension of particles/organelles is made in a suitable buffer or in distilled water.
- (2) Place a drop (~ 5 –10 μ l) of the suspension on to a carbon-formvar glow discharged grid.
- (3) When the suspension has partly dried the grid is washed by touching it three times to the surface of a drop of distilled water.
- (4) Remove excess water by touching the grid to a filter paper.
- (5) A small drop of stain is then applied to the grid.

- (6) After 10 s the excess stain is removed by touching the edge to a filter paper. The sample is wicked to dryness, dried at room temperature and viewed in the TEM.

Alternatively, sequential droplets of; sample, stain, wash can be laid out on a hydrophobic surface (dental wax or parafilm). The carbon formvar TEM grid can be moved between each droplet with short timed exposures to complete the staining procedure.

Negative Staining for Diagnosis of Fecal Samples

Make a 10%–20% suspension of feces in PBS. Centrifuge at 3000 rpm for 30 min to clarify. Collect the supernatant (i.e., the fecal extract) and store at 4°C until EM examination has been completed. Original fecal specimens and extracts may be stored long term at –40°C.

Fecal extracts are examined by one of the following methods.

- (1) **Ultracentrifugation**
Centrifuge 2 ml fecal extract at 20,000 rpm for one hour. Tip off the supernatant and drain the tube well. Reconstitute the deposit in a few drops of distilled water. Mix a drop of this suspension with an equal volume of 3% phosphotungstic acid pH 6.3. Place a drop of mixture on a formvar-carbon coated grid and then touch a piece of filter paper to the edge of the grid to blot dry. Examine the grid in the electron microscope at an instrument magnification around $\times 30,000$ to $\times 60,000$.
If fecal specimens are very fatty and do not adhere to the grid well, mix one-part resuspended pellet with one part 0.05% bovine plasma albumin. Add one-part stain, place a drop on the grid and blot dry.
- (2) **Lyphogel method**
Weigh out 0.1 g lyphogel into a small screw capped bottle. Add 0.55 ml fecal extract. Leave at room temperature for four hours or at 4°C overnight. Place a drop of the residual fluid on a formvar-carbon-coated grid. Blot off the excess with a piece of filter paper. Wash the grid with 1–2 drops of distilled water and blot. Apply a drop of negative stain to the grid and again remove excess stain with filter paper. Examine grids in the microscope.
- (3) **Sucrose method**
Place 4 ml sucrose solution (30% w/v in distilled water) in a centrifuge tube. Layer 1 ml fecal extract onto the sucrose. Centrifuge at 40,000 rpm for two hours. Drain the tubes well – use a swab or tissue if necessary, to ensure that all excess sucrose solution has been removed. Reconstitute the pellet in a few drops of distilled water and stain as in method 1.
These methods are suitable for the detection of most of the usual gastroenteritis viruses eg rotavirus, adenovirus, astrovirus, etc., and are usually all that are required for examining fecal specimens from babies. Further concentration on cesium chloride gradients may be required to detect small round viruses and in particular the small, round, featureless, parvovirus like particles which are more usually associated with gastroenteritis in older children and adults. This method is used in addition to one of the three methods already described.
- (4) **Cesium chloride gradients**
Place 2 ml fecal extract in a centrifuge tube and top up with phosphate buffered saline (PBS). Centrifuge at 40,000 rpm for one hour. Resuspend the deposit in 0.3 ml distilled water. Place 4.5 ml cesium chloride solution in a centrifuge tube (Cesium chloride is made up in distilled water to give a starting density of 1.38g/cc. Cesium chloride solution can be obtained from BDH as a 60% w/w solution for ultracentrifuge work. This solution diluted to 28% in distilled water gives a suitable starting concentration).
Lift the grid up with a pair of forceps and stain by placing a drop of phosphotungstic acid on the grid and blotting dry as before. Examine the grids in the microscope.

Preparation of Agarose Slides

Place 2 ml agarose (0.9% in distilled water) on a microscope slide. Allow the agarose to set and leave in a damp petri dish at 4°C for at least one hour before use. One slide will accommodate three grids satisfactorily. Cesium chloride diffuses into the agarose leaving virus particles attached to the grid (Fig. 3).

A general working assumption is that the threshold of visibility for virus particles is approximately 10^6 particles per ml. Further direct concentration of samples directly onto the TEM grid is possible. The Airfuge by Beckman Colter equipped with an EM-90 Electron Microscopy Particle Counting Rotor will concentrate up to 6 separate samples (100 μ l) directly onto the EM grid and significantly improves the detection sensitivity of DEM.

Limitations of Traditional Processing Techniques and Advanced Protocols

Traditional EM processing strategies introduce artefacts (perturbations to structure) that affect tissue structure, e.g., by shrinkage or swelling of the tissue under examination, the shrinkage of cellular organelles, and/or the extraction or redistribution of cellular constituents such as lipids, proteins and DNA. In addition, most chemical fixatives react with proteins and cross-link peptide chains as part of their action. These reactions can be highly deleterious to epitopes, significantly compromising immunohistochemical studies.
